The letter T, at first used to designate this star, will be properly applied to another variable also discovered by Ceraski, the place of which for 1855·0 is in R.A. 21h. 7m. 33s., Decl. + 67° 54′·4, which seems to have a period of about 400 days, and was at a maximum on December 30, 1880.

PHYSICAL NOTES

IN the *Journal* of the Franklin Institute Prof. S. W. Robinson has recently described some experiments upon the effect produced upon sound-waves by repeated oblique reflections at membranes forming the boundary of two gaseous media. These experiments, as far as they go, would appear to show that after repeated reflection at oblique surfaces set in vertical planes a sound-wave acquires new properties by virtue of which it is reflected at another such oblique surface with an intensity which is a maximum if this surface be also in a vertical plane, and a minimum if the surface be equally inclined to the direction of propagation of the wave, but turned through a right angle about that direction as an axis. If this be indeed established as an experimental result it is equivalent to a proof that sound-waves can be *polarised* by reflection. The apparatus consisted of a series of L-shaped tubes of tin plate, one inch in diameter and three inches long, the parts joined at an obtuse angle, but having the outer angle cut away and covered by a thin membrane. This membrane was fixed so that a sound-wave coming in either direction should be incident on it at the angle of suppo ed maximum polarisation, the angle being calculated by Brewster's Law so that its tangent should represent the ratio between the velocities of wave-propagation in the two media, namely, coal-gas within, air without (14 : 11). The series of tubes was so set that at first the membranes were all parallel, and then a "pulse" was sent along the tube in the following manner :—The initial and final openings were closed by membranes stretched across the tubes orthogonally. Against each a small ball of ivory or glass was hung by a thread. The ball at one end was raised to a given height and dropped on to the membrane, and the impulse given to the ball at the other end was noted. Then the second half of the system was turned round so that the membranes of this portion were at right angles to their former position, and the ball was again dropped. The impulses received on the second ball were in general feebler when the second system, or "analyser," stood at right-angles to the first system, or "polariser," the diminution varying in different experiments from 16 to 38 per cent. No diminution was observable when the interior of the tube was filled with air instead of coal-gas. It remains to be seen whether the results are capable of being reproduced under other circumstances, or whether they are due to some mechanical peculiarity of Prof. Robinson's apparatus. Whether this be so or not we must absolutely reject the very unwarranted conclusion at which Prof. Robinson arrives, namely, that the vibrations of light as well as of sound are longitudinal until they are polarised, and that they become transversal only in the act of polarisation.

M. MERCADIER has examined the resistance of selenium at different temperatures, using for this purpose a photophonic receiver of selenium spread between the edges of platinum sheets, the resistance being measured in the dark by the ordinary bridge-method. The receiver, which had been well annealed, had at 15° C. a resistance of 54,000 ohms. This amount decreased as the temperature rose with great regularity to 36° C., when its resistance was less than 1500 ohms. From this point the diminution of resistance was less rapid ; but at about 125° C. it had fallen to less than 500 ohms, rising slightly to 163° C., from which it again fell as the temperature was raised to 208°. These results accord with the earlier experiments of Werner Siemens.

M. LIPPMANN finds (*Jour. de Phys.*, May) that galvanic polarisation, which modifies so much the capillary properties of a metallic surface, causes no perceptible variation of its optical properties. He directed a beam of polarised light towards a platinum or silver mirror in acidulated water, or copper sulphate solution, and it was received, after reflection, in a Jamin quartz compensator, followed by an analyser-Nicol. The dark fringe in the compensator was not displaced when the mirror was included in the circuit of a Daniell or Bunsen element, and the current passed. Again, Newton's rings, formed by a glass plate on the platinum surface, and observed under various incidences, showed no displacement when the polarising current passed. (M. Lippmann adds some observations as to the mode of production of gas-bubbles by electrolysis.)

A FEW years ago M. Montigny called attention to the fact that the scintillation of stars is considerably increased during aurora borealis. Further data on this subject are afforded in a recent issue of the Belgian Academy's *Bulletin*, No. 3. *Inter alia*, he has observed that the phenomenon is more pronounced in winter than in summer, and that stars in the northern region

show the increased scintillation most. The author's general conclusion is that the effect is not one due to direct influence of the electro-magnetic light of aurora on the scintillation itself, but to disturbances (probably a cooling) which coincide with the appearance of aurora in the upper regions of the air, traversed by the star-rays.

An acoustical apparatus for lecture purposes, devised by Dr. Maschke (*Wied. Ann.* No. 5), consists of a longish graduated piece of wood on adjustable supports, and having a longitudinal groove in its upper surface, in which a glass tube is placed. At the end of the wooden piece is a screw arrangement supporting a thin steel rod which enters the tube, and has at its end a (vertical) ring with collodion membrane, against which hangs a little ball of shellac by a cocoon-fibre from the upper border. The tube may be made a closed one by means of a felt-covered piston. When the tube is sounded by means of a suitable tuning-fork, the shellac ball shows pendulum-motions, if not at a nodal point. The effects may be projected on a screen.

The passivity of iron has been studied under new conditions by M. Bibart (*Jour. de Phys.*, May), and he considers it is not produced by a layer of insoluble sub-nitrate, as some physicists have thought, since the previous action of nitric acid is not necessary. Still less is it due to a formation of bioxide of nitrogen. It is produced by any cause which tends to oxidise iron, and destroyed by any cause which tends to deoxidise it. It is due then either to a layer of oxide or a layer of oxygen. The oxides formed on the surface may preserve it by their very presence, furnishing a sort of unattackable varnish, or they may preserve it like platinum, liberating, on the denuded parts, a protective layer of oxygen. The passivity of iron from contact of platinum seems to be produced at first by a simple layer of oxygen condensed on the platinum surface (a simple shock destroys it). But by degrees a layer of oxide is formed, and the iron then loses its passivity much less readily than before.

GEOGRAPHICAL NOTES

Dr. Schweinfurth, who left Suez for Socotra on February 23, returned on June 19. From the *Egyptian Gazette* we learn that his voyage to the island in a native vessel lasted one month (with calls). He was a month on the island. The rich flora yielded many new species. The mountains are well wooded, and covered with a more luxuriant vegetation than Mount Etna. The climate is exceptionally temperate, and the natives are inoffensive, greater security being experienced everywhere than in any part of uncivilised Africa. On the approach of the south-west monsoon Dr. Schweinfurth had to leave, and in a miserable native vessel he tried to reach the Arabian coast opposite Socotra. It was found impossible to get to the east of Aden, and in H.M.S. *Dragon*, which was met, the explorer was conveyed to that place. Dr. Schweinfurth has brought with him a rich botanical collection, including some living plants which he will try to acclimatise in his garden at Cairo.

The Polar relief ship *Rodgers*, Lieut. Berry, sailed from San Francisco on June 16 in search of the *Jeannette*. She will first cruise to St. Berry, then proceed to Petropaulovsky, then cross to St. Michael's in Alaska to coal, thence to St. Lawrence Bay and along the coast of Northern Siberia, making inquiries of the natives; then from Cape Serge to Kamon, where letters will be left with some natives; then north to Herald Island, hunting well over for cairns. It is intended next to go along the southern shore of Wrangel Land, and seek a harbour to winter in. The north-east and west coasts will be examined in sledge parties. Lieut. Berry means to return, if possible, by the second year.

Instructions have now been issued by Brigadier-General Hazen, of the U.S. Signal Office, to the commanding officers of the two expeditionary forces about to be sent out to establish permanent stations of observation in Polar regions. Lieut. Greely commands one of these forces, which goes to the neighbourhood of the coal-seam discovered near Lady Franklin Bay in 1875. The steamer will directly return (with a transcript of observations during the voyage), and the party landed will proceed to erect dwelling-houses and observatories, after which a sledge party will proceed to the high land near Cape Joseph Henry. It is intended that the permanent station shall be visited in 1882 and 1883 by a steam-sealer or other vessel with stores, &c., but directions in case of failure are supplied. Lieut. Ray commands the other expedition, which will sail from San Francisco for Point Barrow, Alaska Territory, and establish there a permanent station to be occupied till the summer of 1884 and visited annually. A great variety of observations will be made by both parties, and the instructions drawn out by the recent Hamburg Conference (with added notes from the U.S. Chief Signal Office) are furnished.

Dr. Gerard Rohlfs delivered an interesting lecture at the meeting of the Berlin Gesellschaft für Erdkunde regarding his last journey in Abyssinia. He was received in a friendly manner by the inhabitants, and he is quite charmed with the hospitality of the Abyssinians. At Debratabor he was received kindly by Negus (Emperor) Johannes, and this was of great importance for his subsequent tour. Rohlfs travelled in a northerly direction to the ancient Portuguese capital Gondar, the residence of the late King Theodore. By means of a pass given to him by the ecclesiastical chief of the city he was able to inspect all the ancient historical buildings of the city. He continued his journey to the north, and after crossing the Takkaze River he reached Artum (Axum?), the ancient former royal residence, with its monuments dating from the period of Ptolemy. In April Rohlfs reached the Nassaur mountain chain, the boundary of Abyssinia, whence he proceeded to Cairo by boat.

The expedition sent out by the French Secretary for Public Instruction to investigate the east coast of Finmarken has arrived at Vadsö after a journey of twenty-one days. The expedition, which is under the command of M. Georges Pouchet, has for its special object to study the natural history of the Varanger Fjord, which is situated at the boundary of the Atlantic and Arctic Oceans. The keeper of the Christiania Royal Zoological Collections joined the expedition at Hammerfest.

The Emperor of Germany has honoured Dr. Oscar Lenz, the well-known African traveller, with the Order of the Crown.

Mr. Sandford Fleming, C.M.G., Engineer-in-Chief of the Canadian Pacific Railroad, is to attend the International Geographical Congress at Venice in the interests of the question of standard time, coupled with which is that of a prime meridian. The former of these subjects is attracting much attention on the other side of the Atlantic, and a paper on it was lately read by Mr. Fleming before the American Society of Civil Engineers at a convention in Montreal, which brought out an interesting discussion, and a committee, consisting of leading railway officials in Canada and the United States, was appointed to examine and report at a future meeting. Dr. Barnard, the President of Columbia College, New York, is to represent the American Meteorological Society on the same subject at a meeting of the Association for the Reform and Codification of the Law of Nations, which is to be held at Cologne in August.

Col. Perrier, a well-known French topographer, has lately been for some time engaged in survey work in the Regency of Tunis, and has prepared a map of the Kroumir country, which will shortly be published by the Dépôt de la Guerre.

Messrs. S. Clarke and J. H. Riley, of the China Inland Mission, whose station is at Chungking, formerly Mr. Colborne Baber's head-quarters, have each lately made important journeys in the Szechuen province. Mr. French, accompanied in one of his journeys by Mr. Broumton, has visited nearly every city in Eastern Yünnan, and has lately started again for the same region. In the course of their journey from Burmah Messrs. Soltan and Stevenson also made extensive journeys in the western part of the Yünnan province.

The steamer *Nordenskjöld* is to start this week for the Gulf of Obi to the assistance of the *Oscar Dickson* and the *Nordland*. The crews of these vessels were all safe on April 23, when five men from the former left for Tobolsk, which they have lately reached.

A letter from Mussuca, on the Lower Congo, states that a Jesuit missionary expedition has been set on foot to penetrate into the far interior. Père Argourd has been sent from the French mission station at Landana to organise a party of about thirty to proceed to Stanley Pool. He tried to procure carriers at Boma, Mussuca, and Noki, but not succeeding there, he went some thirteen miles inland to King Kangan Pecca, with a view to secure his aid. This was readily obtained by a truly missionary present of two gallons of rum, and Père Argourd returned with eight men and the promise that seventeen more should be sent shortly. The men however ran away the next day, and, yielding to circumstances, Père Argourd has resolved to proceed to Stanley Pool by M. de Brazza's route up the Ogowé.

MR. CRUDGINGTON, of the Baptist Congo Expedition, has just returned to England for a short time, and reports that by now Messrs. Comber and Bentley will have formed a first station at Isangila, Mr. Stanley's second post, and will at once push on to Mbu, some sixty or seventy miles further along the north bank of the Congo, where the the second station will be erected. It is for this navigable portion of the river that a steel boat is required, so as to avoid the Basundi. In his late journey up the Congo Mr. Crudgington found these people warlike and troublesome, as Mr. Stanley had done, and they were a source of perpetual anxiety to him. The practicability of utilising this part of the river is shown by the fact that Mr. Crudgington and his party went over it in heavy, clumsy, native canoes; but from Mbu the expedition will have to go to Stanley Pool by land, as the rapids and falls render the river quite unnavigable. The plans of the expedition are now on such an extended scale that six additional missionaries will be required—two for San Salvador, one for the depot at Mussuca on the Lower Congo, one each for Isangila and Mbu, and four for Stanley Pool, so that occasional journeys may be made higher up the Congo. The steel boat required by the expedition has been presented by an anonymous donor at a cost of about 400*l*. It has been built in London from drawings furnished by Mr. H. M. Stanley.

THE *Times* last week published an exceedingly interesting letter on trade and exploration on the Congo from a private correspondent at the mouth of the Ogowé. Speaking of M. Savorgnan de Brazza, the writer says that he has done much to open up the country between the Ogowé and the Congo, that he purchased a large tract of country near the sources of the former river at a very cheap rate, erected a station, and left a white man in charge. He is said to have purchased villages as they stood, freed a great many slaves, and engaged them at monthly wages to cultivate the plantations and keep the ground in order. He seems to have been regarded as the apostle of freedom in the country; troops of slaves came flocking to him to be freed, and his visit is regarded as having struck a blow at slavery in West Africa. The writer gives a very different picture of the state of affairs on the Belgian road along the north bank of the Congo. It may be interesting to mention, the observations respecting the light in which M. de Brazza is viewed by the natives are fully confirmed by a letter from a Roman Catholic missionary who accompanied him up the Ogowé last December.

WHIRLED ANEMOMETERS [1]

IN the course of the year 1872 Mr. R. H. Scott, F.R.S., suggested to the Meteorological Committee the desirability of carrying out a series of experiments on anemometers of different patterns. This suggestion was approved by the Committee, and in the course of the same year a grant was obtained by Mr. Scott from the Government grant administered by the Royal Society for the purpose of defraying the expenses of the investigation. The experiments were not however carried out by Mr. Scott himself, but were intrusted to Mr. Samuel Jeffery, then Superintendent of the Kew Observatory, and Mr. G. M. Whipple, then First Assistant, the present Superintendent.

The results have never hitherto been published, and I was not aware of their nature till on making a suggestion that an anemometer of the Kew Standard pattern should be whirled in the open air, with a view of trying that mode of determining its proper factor, Mr. Scott informed me of what had already been done, and wrote to Mr. Whipple, requesting him to place in my hands the results of the most complete of the experiments, namely, those carried on at the Crystal Palace, which I accordingly obtained from him. The progress of the inquiry may be gathered from the following extract from Mr. Scott's report in returning the unexpended balance of the grant:—

"The comparisons of the instruments tested were first instituted in the garden of the Kew Observatory. This locality was found to afford an insufficient exposure.

"A piece of ground was then rented and inclosed within the Old Deer Park. The experiments here showed that there was a considerable difference in the indications of anemometers of different sizes, but it was not possible to obtain a sufficient range of velocities to furnish a satisfactory comparison of the instruments. Experiments were finally made with a rotating apparatus, a steam merry-go-round, at the Crystal Palace, which led to some results similar to those obtained by exposure in the Deer Park.

"The subject has however been taken up so much more thoroughly by Doctors Dohrandt and Thiesen (*vide* "Repertorium für Meteorologie," vols. iv. and v.), and by Dr. Robinson in Dublin, that it seems unlikely that the balance would ever be expended by me. I therefore return it with many thanks to the Government Grant Committee.

"The results obtained by me were hardly of sufficient value to be communicated to the Society."

On examining the records it seemed to me that they were well deserving of publication, more especially as no other experiments of the same kind have, so far as I know, been executed on an anemometer of the Kew standard pattern. In 1860 Mr. Glaisher made experiments with an anemometer whirled round in the open air at the end of a long horizontal pole,[2] but the anemometer was of the pattern employed at the Royal Observatory, with hemispheres of 3·75 inches diameter and arms of 6·725 inches, measured from the axis to the centre of a cup, and so was considerably smaller than the Kew pattern. The experiments of Dr. Dohrandt and Dr. Robinson were made in a building, which has the advantage of sheltering the anemometer from wind, which is always more or less fitful, but the disadvantage of creating an eddying vorticose movement in the whole mass of air operated on; whereas in the ordinary employment of the anemometer the eddies it forms are carried away by the wind, and the same is the case to a very great extent when an anemometer is whirled in the open air in a gentle breeze. Thus, though Dr. Robinson employed among others an anemometer of the Kew pattern, his experiments and those of Mr. Jeffery are not duplicates of each other, even independently of the fact that the axis of the anemometer was vertical in Mr. Jeffery's and horizontal in Dr. Robinson's experiments; so that the greater completeness of the latter does not cause them to supersede the former.

In Mr. Jeffery's experiments the anemometers operated on were mounted a little beyond and above the outer edge of one of the steam merry-go-rounds in the grounds of the Crystal Palace, so as to be as far as practicable out of the way of any vortex which it might create. The distance of the axis of the anemometer from the axis of the "merry" being known, and the number of revolutions (n) of the latter during an experiment counted, the total space traversed by the anemometer was known. The number (N) of *apparent* revolutions of the anemometer, that is, the number of revolutions *relatively to the merry*, was recorded on a dial attached to the anemometer, which was read at the beginning and end of each experiment. As the machine would only go round one way the cups had to be taken off and replaced in a reverse position, in order to reverse the direction of revolution of the anemometer. The *true* number of revolutions of the anemometer was, of course, $N + n$, or $N - n$, according as the rotations of the anemometer and the machine were in the same or opposite directions.

The horizontal motion of the air over the whirling machine during any experiment was determined from observations of a dial anemometer with 3-inch cups on 8-inch arms, which was fixed on a wooden stand in the same horizontal plane as that in which the cups of the experimental instrument revolved, at a distance estimated at about 30 feet from the outside of the whirling frame. The motion of the centres of the cups was deduced from the readings of the dial of the fixed anemometer at the beginning and end of each experiment, the motion of the air being assumed as usual to be three times that of the cups.

The experiments were naturally made on fairly calm days, still the effect of the wind, though small, is not insensible. In default of further information, we must take its velocity as equal to the mean velocity during the experiment.

Let V be the velocity of the anemometer, W that of the wind, θ the angle between the direction of motion of the anemometer and that of the wind. Then the velocity of the anemometer relatively to the wind will be—

$$\sqrt{V^2 - 2VW\cos\theta + W^2} \quad . \quad . \quad . \quad . \quad . \quad (a)$$

The mean effect of the wind in a revolution of the merry will be different according as we suppose the moment of inertia of the anemometer very small or very great.

If, as is practically the case, W be small as compared with V, the correction to be added to V on account of the wind may be

[1] "Discussion of the Results of some Experiments with Whirled Anemometers." Paper read at the Royal Society, May 12, by Prof. G. G. Stokes, Sec. R.S.

[2] "Greenwich Magnetical and Meteorological Observations," 1862, Introduction, p. li.

shown to be $W^2/4V$ on the first supposition, and $3W^2/4V$ on the second.

Three anemometers were tried, namely, one of the old Kew standard pattern, one by Adie, and Kraft's portable anemometer. Their dimensions, &c., were as follows :—

(*a*) *The Old Kew Standard.*—Diameter of arms between centres of cups 48 inches; diameter of cups 9 inches. Fixed to machine at 22·3 feet from the axis of revolution.

(*β*) *Adie's Anemometer.*—Diameter of arms between centres of cups 13·4 inches; diameter of cups 2·5 inches. Fixed to machine at 20·7 feet from the axis of revolution.

(*γ*) *Kraft's Portable Anemometer.*—Diameter of arms between centres of cups 8·3 inches; diameter of cups 3·3 inches. Fixed to machine at 19·10 feet from the axis of revolution.

With each anemometer the experiments were made in three groups, with high, moderate, and low velocities respectively, averaging about 28 miles an hour for the high, 14 for the moderate, and 7 for the low. Each group again was divided into two subordinate groups, according as the cups were direct, in which case the directions of rotation of the merry and of the anemometer were opposite, or reversed, in which case the directions of the two rotations were the same.

The data furnished by each experiment were: the time occupied by the experiment, the number of revolutions of the merry, the number of *apparent* revolutions of the anemometer, given by the difference of readings of the dial at the beginning and end of the experiment, and the space S passed over by the wind, deduced from the difference of readings of the fixed anemometer at the beginning and end of the experiment.

The object of the experiment was of course to compare the mean velocity of the centres of the cups with the mean velocity of the air relatively to the anemometer. It would have saved some numerical calculation to have compared merely the spaces passed through during the experiment; but it seemed better to exhibit the velocities in miles per hour, so as to make the experiments more readily comparable with one another, and with those of other experimentalists. In the reductions I employed 4-figure logarithms, so that the last decimal in V in the tables cannot quite be trusted, but it is retained to match the correction for W., which it seemed desirable to exhibit to 0·01 mile.

On reducing the experiments with the low velocities I found the results extremely irregular. I was subsequently informed by Mr. Whipple that the machine could not be regulated at these low velocities, for which it was never intended, and that it sometimes went round fast, sometimes very slowly. He considered that the experiments in this group were of little, if any, value, and that they ought to be rejected. They were besides barely half as numerous as those of the moderate group. I have accordingly thought it best to omit them altogether.

In the complete paper tables are then given containing the reduced results of the individual experiments, and from them the mean results for the high and moderate velocities are collected in the following table, in which are also inserted the mean errors :—

Anemometer.	Directions of rotation.	High velocities. Mom. inert. small. p. c.	m. e.	Mom. inert. large. p. c.	m. e.	Moderate velocities. Mom. inert. small. p. c.	m. e.	Mom. inert. large. p. c.	m. e.
Kew.	Opposite ...	122·6	2·4	121·9	2·3	115·1	4·9	113·2	5·2
	Alike	118·4	2·9	117·5	2·8	109·7	4·5	108·5	5·1
	Mean ...	120·5	...	119·7	...	112·4	...	110·8	
Adie.	Opposite ...	95·1	2·3	94·2	2·3	88·5	4·5	86·8	5·0
	Alike	98·0	6·5	97·3	6·5	82·6	7·3	81·0	7·3
	Mean ...	96·5	...	95·7	...	85·5	...	83·9	
Kraft.	Opposite ...	101·5	2·6	100·8	2·5	89·1	4·8	86·9	5·1
	Alike	100·8	1·2	99·4	1·3	87·8	5·0	86·0	6·0
	Mean ...	101·1	...	100·1	...	88·4	...	86·4	

The mean errors exhibited in the above table show no great difference according as we suppose the moment of inertia of the anemometer small or large in correcting for the wind. From the mean errors we may calculate nearly enough, by the usual formulæ, the probable errors of the various mean percentages for rotations opposite and alike. The probable errors of these mean percentages come out as follows :—

Kew, 1·0 for high velocities; 2·7 for moderate velocities.
Adie, 1·5 ,, ,, 2·0 ,, ,,
Kraft, 0·9 ,, ,, 1·8 ,, ,,

These probable errors are so small that it appears that for the high and even for the moderate velocities the experiments are extremely trustworthy, except in so far as they may be affected by *systematic* sources of error.

It may be noticed that the difference of the percentages according as the directions of rotation of the anemometer and of the merry are opposite or alike is greatest for the Kew, in which the ratio of r to R is greatest, r denoting the radius of the arm of the anemometer, and R the distance of its axis from the axis of revolution of the machine, and appears to be least (when allowance is made for the two anomalous experiments in the group "Adie H + ") for the Kraft, for which r/R is least. In the Kraft indeed the differences are roughly equal to the probable errors of the means. In these whirling experiments r/R is always taken small, and we might expect the correction to be made on account of the finiteness of R to be expressible in a rapidly converging series according to powers of r/R, say—

$$A' \frac{r}{R} + B'\left(\frac{r}{R}\right)^2 + C'\left(\frac{r}{R}\right)^3 + \cdots$$

We may in imagination pass from the case of rotations opposite to that of rotations alike, by supposing R taken larger and larger in successive experiments, altering the angular velocity of revolution so as to preserve the same linear velocity for the anemometer, and supposing the increase continued until R changes sign in passing through infinity, and is ultimately reduced in magnitude to what it was at first. The ideal case of $R = \infty$ is what we aim at, in order to represent the motion of a fixed anemometer acted on by perfectly uniform wind by that of an anemometer uniformly impelled in a rectilinear direction in perfectly still air. We may judge of the magnitude of the leading term in the above correction, provided it be of an odd order, by that of the difference of the results for the two directions of rotation. Unless therefore we had reason to believe that A' were 0, or at least very small compared with B', we should infer that the whole correction for the finiteness of R is very small, and that it is practically eliminated by taking the mean of the results for rotations opposite and rotations alike.

We may accept, therefore, the mean results as not only pretty well freed from casual irregularities which would disappear in the mean of an infinite number of experiments, but also, most probably, from the imperfection of the representation of a rectilinear motion of the anemometer by motion in a circle of the magnitude actually employed in the experiments.

Before discussing further the conclusions to be drawn from the results obtained, it will be well to consider the possible influence of systematic sources of error.

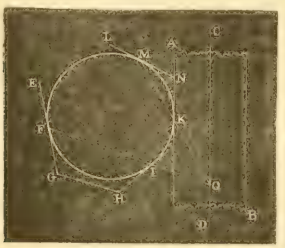
1. *Friction.*—No measure was taken of the amount of friction, nor were any special appliances used to reduce it; the anemometers were mounted in the merry just as they are used in actual registration. Friction arising from the weight is guarded against as far as may be in the ordinary mounting, and what remains of it would act alike in the ordinary use of the instrument and in the experiments, and as far as this goes, therefore, the experiments would faithfully represent the instrument as it is in actual use. But the bearings of an anemometer have also to sustain the lateral pressure of the wind, which in a high wind is very considerable; and the construction of the bearing has to be attended to in order that this may not produce too much friction. So far the whirled instrument is in the same condition as the fixed. But besides the friction arising from the pressure of the artificial wind, a pressure which acts in a direction tangential to the circular path of the whirled anemometer, there is the pressure arising from the centrifugal force. The highest velocity in the experiments was about thirty miles an hour, and at this rate the centrifugal force would be about three times the weight of the anemometer. This pressure would considerably exceed the former, at right angles to which it acts, and the two would compound into one equal to the square root of the sum of their squares. The resulting friction would exceed a good deal that arising from the pressure of the wind in a fixed anemometer with the same velocity of wind, natural or artificial, and would

sensibly reduce the velocity registered, and accordingly raise the coefficient which Dr. Robinson denotes by m, the ratio, namely, of the velocity of the wind to the velocity of the centres of the cups. It may be noticed that the percentages collected in the above table are very distinctly lower for the moderate velocities than for the high velocities. Such an effect would be produced by friction; but how far the result would be modified if the extra friction due to the centrifugal force were got rid of, and the whirled anemometer thus assimilated to a fixed anemometer, I have not the means of judging, nor again how far the percentages would be still further raised if friction were got rid of altogether.

Perhaps the best way of diminishing friction in the suppport of an anemometer is that devised and employed by Dr. Robinson, in which the anemomeser is supported near the top on a set of spheres of gun-metal contained in a box with a horizontal bottom and vertical side which supports and confines them. For vertical support this seems to leave nothing to be desired, but when a strong lateral pressure has to be supported as well as the weight of the instrument, it seems to me that a slight modification of the mode of support of the balls might be adopted with advantage. When a ball presses on the bottom and vertical side of its box, and is at the same time pressed down by the horizontal disk attached to the shaft of the anemometer which rests on the balls, it revolves so that the instantaneous axis is the line joining the points of contact with the fixed box. But if the lateral force of the wind presses the shaft against the ball the ball cannot simply roll as the anemometer turns round, but there is a slight amount of rubbing.

This however may be obviated by giving the surfaces where the ball is in contact other than vertical or horizontal direction.

Let A B be a portion of the cylindrical shaft of an anemometer; C D the axis of the shaft; E F G H I a section of the fixed box or cup containing the balls; L M N a section of a conical surface fixed to the shaft by which the anemometer rests on its balls; F I K M a section of one of the balls; F, I, the points of contact



of the ball with the box; M the point of contact with the supporting cone; K the point of contact, or all but contact, of the ball with the shaft. The ball is supposed to be of such size that when the anemometer simply rests on the balls by its own weight, being turned perhaps by a gentle wind, there are contacts at the points M, F, I, while at K the ball and shaft are separated by a space which may be deemed infinitesimal. Lateral pressure from a stronger wind will now bring the shaft into contact with the ball at the point K also, so that the box on the one hand and the shaft with its appendage on the other will bear on the ball at four points. The surface of the box, as well as that on the cone L N, being supposed to be one of revolution round C D, those four points will be situated in a plane through C D, which will pass of course through the centre of the ball.

If the ball rolls without rubbing at any one of the four points F, I, K, M as the anemometer turns round, its instantaneous axis must be the line joining the points of contact F, I, with the fixed box. But as at M and K likewise there is nothing but rolling, the instantaneous motion of the ball may be thought of as one in which it moves as if it were rigidly connected with the shaft and its appendage, combined with a rotation over L N A B supposed fixed. For the two latter motions the instantaneous axes are C D, M K respectively. Let M K produced cut C D in O. Then since the instantaneous motion is compounded of rotations round two axes passing through O, the instantaneous axis must pass through O. But this axis is F I. Therefore F I must pass through O. Hence the two lines F I, M K must intersect the axis of the shaft in the same point, which is the condition to be satisfied in order that the ball may roll without rubbing, even though impelled laterally by a force sufficient to cause the side of the shaft to bear on it. The size of the balls and the inclinations of the surfaces admit of considerable latitude subject to the above condition. The arrangement might suitably be chosen something like that in the figure. It seems to me that a ring of balls constructed on the above principle would form a very effective upper support for an anemometer whirled with its axis vertical. Possibly the balls might get crowded together on the outer side by the effect of centrifugal force. This objection, should it be practically found to be an objection, would not of course apply to the proposed system of mounting in the case of a fixed anemometer. Below, the shaft would only require to be protected from lateral motion, which could be done either by friction wheels or by a ring of balls constructed in the usual manner, as there would be only three points of contact.

2. *Influence on the Anemometer of its own Wake.*—By this I do not mean the influence which one cup experiences from the wake of its predecessor, for this occurs in the whirling in almost exactly the same way as in the normal use of the instrument, but the motion of the air which remains at any point of the course of the anemometer in consequence of the disturbance of the air by the anemometer when it was in that neighbourhood in the next preceding and the still earlier revolutions of the whirling instrument.

It seems to me that in the open air, where the air impelled by the cups is free to move into the expanse of the atmosphere, instead of being confined by the walls of a building, this must be but small, more especially as the wake would tend to be carried away by what little wind there might be at the time. On making some inquiries from Mr. Whipple as to a possible vorticose movement created in the air through which the anemometer passed, he wrote as follows:—"I feel confident that under the circumstances the tangential motion of the air at the level of the cups was so small as not to need consideration in the discussion of the results. As in one or two points of its revolution the anemometer passed close by some small trees in full leaf, we should have observed any eddies or artificial wind had it existed, but I am sure we did not."

3. *Influence of the Variation of the Wind; first, as regards Variations which are not Rapid.*—During the twenty or thirty minutes that an experiment lasted there would of course be numerous fluctuations in the velocity of the wind, the mean result of which is alone recorded. The period of the changes (by which expression it is not intended to assert that they were in any sense regularly periodic), might be a good deal greater than that of the merry, or might be comparatively short. In the high velocities, at any rate, in which one revolution took only three or four seconds, the supposition that the period of the changes was large compared with one revolution is probably a good deal nearer the truth than the supposition that it is small.

On the former supposition the correction for the wind during two or three revolutions of the merry would be given by the formulæ already employed, taking for W its value at the time. Consequently the total correction will be given by the formulæ already used if we substitute the mean of W^2 for the square of mean W. The former is necessarily greater than the latter, but how much we cannot tell without knowing the actual variations. We should probably make an outside estimate of the effect of the variations if we supposed the velocity of the wind twice the mean velocity during half the duration of the experiment, and nothing at all during the remainder. On this supposition the mean of W^2 would be twice the square of mean W, and the correction for the wind would be doubled. At the high velocities of revolution, the whole correction for the wind is so very small that the uncertainty arising from variation as above explained is of little importance, and even for the moderate velocities it is not serious.

4. *Influence of Rapid Variations of the Wind.*—Variations of which the period is a good deal less than that of the revolutions of the whirling instrument act in a very different manner. The smallness of the corrections for the wind hitherto employed depends on the circumstance that with uniform wind, or even with variable wind, when the period of variation is a good deal greater than that of revolution of the merry, the terms depending on the first power of W, which letter is here used to denote the momentary velocity of the wind, disappear in the mean of a revolution. This is not the case when a particular velocity of wind belongs only to a particular part of the circle described by

the anemometer in one revolution. In this case there will in general be an outstanding effect depending on the first power of W, which will be considerably larger than that depending on W^2. Thus suppose the velocity of whirling to be thirty miles an hour, and the average velocity of the wind three miles an hour, the correction for the wind supposed uniform, or if variable, then with not very rapid variations, will be comparable with 1 per cent. of the whole; whereas, with rapid variations, the effect in any one revolution may be comparable with 10 per cent. There is, however, this important difference between the two: that whereas the correction depending on the square leaves a positive residue, however many experiments be made, the correction depending on the first power tends ultimately to disappear, unless there be some cause tending to make the average velocity of the wind different for one azimuth of the whirling instrument from what it is for another. This leads to the consideration of the following conceivable source of error.

5. *Influence of Partial Shelter of the Whirling Instrument.*—On visiting the merry-go-round at the Crystal Palace, I found it mostly surrounded by trees coming pretty near it, but in one direction it was approached by a broad open walk. The consequence is that the anemometer may have been unequally sheltered in different parts of its circular course, and the circumstances of partial shelter may have varied according to the direction of the wind. This would be liable to leave an uncompensated effect depending on the first power of W. I do not think it probable that any large error was thus introduced, but it seemed necessary to point out that an error of the kind may have existed.

The effect in question would be eliminated in the long run if the whirling instrument were capable of reversion, and the experiments were made alternately with the revolution in one direction, and the reverse. For then, at any particular point of the course at which the anemometer was more exposed to wind than on the average, the wind would tend to increase the velocity of rotation of the anemometer for one direction of revolution of the whirling instrument just as much, ultimately, as to diminish it for the other. Mere reversion of the cups has no tendency to eliminate the error arising from unequal exposure in different parts of the course. And even when the whirling instrument is capable of reversion it is only very slowly that the error arising from partial shelter is eliminated compared with that of irregularities in the wind; of those irregularities, that is to say, which depend on the first power of W. For these irregularities go through their changes a very great number of times in the course of an experiment lasting perhaps half an hour, whereas the effect of partial shelter acts the same way all through one experiment. It is very desirable therefore that in any whirling experiments carried on in the open air, the condition of the whirling instrument as to exposure or shelter should be the same all round.

The trees, though taller than the merry when I visited the place last year, were but young, and must have been a good deal lower at the time that the experiments were made. Mr. Whipple does not think that any serious error is to be apprehended from exposure of the anemometer during one part of its course and shelter during another.

From a discussion of the foregoing experiments it seems to me that the following conclusions may be drawn:—

1. That, at least for high winds, the method of obtaining the factor for an anenometer, which consists in whirling the instrument in the open air, is capable, with proper precautions, of yielding very good results.

2. That the factor varies materially with the pattern of the anemometer. Among those tried, the anemometers with the larger cups registered the most wind, or in other words required the lowest factors to give a correct result.

3. That with the large Kew pattern, which is the one adopted by the Meteorological Office, the register gives about 120 per cent. of the truth, requiring a factor of about 2·5, instead of 3. Even 2·5 is probably a little too high, as friction would be introduced by the centrifugal force, beyond what occurs in the normal use of the instrument.

4. That the factor is probably higher for moderate than for high velocities; but whether this is solely due to friction the experiments do not allow us to decide.

Qualitatively considered, these results agree well with those of other experimentalists. As the factor depends so much on the pattern of the anemometer it is not easy to find other results with which to compare the actual numbers obtained, except in the case the Kew standard. The results obtained by Dr. Robinson, by rotating an anemometer of this pattern without friction purposely applied are given at pp. 797 and 799 of the *Phil. Trans.* for 1878. The mean of a few taken with velocities of about 27 miles an hour in still air gave a factor 2·36, instead of 2·50, as got from Mr. Jeffery's experiments. As special anti-friction appliances were used by Dr. Robinson, the friction in Mr. Jeffery's experiments was probably a little higher. If such were the case the factor ought to come out a little higher than in Dr. Robinson's experiments, which is just what it does. As the circumstances of the experiments were widely different with respect to the vorticose motion of the air produced by the action of the anemometer in it, we may, I think, conclude that no very serious error is to be apprehended on this account.

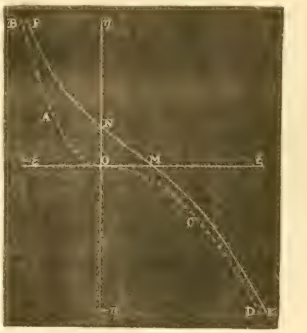
In a later paper (*Phil. Trans.* for 1880, p. 1055), Dr. Robinson has determined the factor for an anemometer (among others) of the Kew pattern by a totally different method, and has obtained values considerably larger than those given by the former method. Thus the limiting value of the factor m corresponding to very high velocities, is given at p. 1063 as 2·826, whereas the limiting value obtained by the former method was only 2·286. Dr. Robinson has expressed a preference for the later results. I confess I have always been disposed to place greater reliance on the results of the Dublin experiments, which were carried out by a far more direct method, in which I cannot see any flaw likely to account for so great a difference. It would be interesting to try the second method in a more favourable locality.

I take this opportunity of putting out some considerations respecting the general formula of the anemometer, which may perhaps not be devoid of interest.

The problem of the anemometer may be stated to be as follows:—Let a uniform wind with velocity V act on a cup anemometer of given pattern, causing the cups to revolve with a velocity v, referred to the centre of the cups, the motion of the cups being retarded by a force of friction F; it is required to determine v as a function of V and F, F having any value from 0, corresponding to the ideal case of a frictionless anemometer, to some limit F_1, which is just sufficient to keep the cups from turning. I will refer to my appendix to the former of Dr. Robinson's papers (*Phil. Trans.* for 1878, p. 818), for the reasons for concluding that F is equal to V^2, multiplied by a function of V/v. Let

$$V : \xi, \qquad F/V^2 = \eta,$$

then if we regard ξ and η as rectangular co-ordinates we have to determine the form of the curve, lying within the positive quadrant $\xi O \eta$, which is defined by those co-ordinates.



We may regard the problem as included in the more general problem of determining v as a function of V and F, where V is positive, but F may be of any magnitude and sign, and therefore v also.[1] Negative values of F mean, of course, that the cups, instead of being retarded by friction, are acted on by an impelling force making them go faster than in a frictionless anemometer, and values greater than F_1 imply a force sufficient to send them round with the concave sides foremost.

[1] Of course v must be supposed not to be so large as to be comparable with the velocity of sound, since then the resistance to a body impelled through air, or having air impinging on it, no longer varies as the square of the velocity.

Suppose now F to be so large, positive or negative, as to make v so great that V may be neglected in comparison with it, then we may think of the cups as whirled round in quiescent air in the positive or usual direction when F is negative, in the negative direction when F is greater than F_1. When F is sufficiently large the resistance may be taken to vary as v^2. For equal velocities v it is much greater when the concave side goes foremost than when the rotation is the other way. For air impinging perpendicularly on a hemispherical cup Dr. Robinson found that the resistance was as nearly as possible four times as great when the concave side was directed to the wind as when the convex side was turned in that direction (*Transactions* of the Royal Irish Academy, vol. xxii. p. 163). When the air is at rest and the cups are whirled round, some little difference may be made by the wake of each cup affecting the one that follows. Still we cannot be very far wrong by supposing the same proportion, 4 to 1, to hold good in this case. When F is large enough and negative, F may be taken to vary as v^2, say to be equal to $-Lv^2$. Similarly, when F is large enough and positive, F may be taken equal to $L'v^2$, where in accordance with the experiment referred to, L′ must be about equal to 4 L. Hence we must have nearly—

$$\eta = -L\xi^2, \text{ when } \xi \text{ is positive and very large;}$$
$$\eta = 4L\xi^2, \quad ,, \quad \text{negative} \quad ,, \quad ,,$$

Hence if we draw the semi-parabola O A B corresponding to the equation $\eta = 4L\xi^2$ in the quadrant $\eta O - \xi$, and the semi-parabola O C D with a latus lectum four times as great in the quadrant $\xi O - \eta$, our curve at a great distance from the origin must nearly follow the parabola O A B in the quadrant $\eta O - \xi$, and the parabola O C D in the quadrant $\xi O - \eta$, and between the two it will have some flowing form such as P N M K. There must be a point of inflection somewhere between P and K, not improbably within the positive quadrant $\xi O \eta$. In the neighbourhood of this point the curve N M would hardly differ from a straight line. Perhaps this may be the reason why Dr. Robinson's experiments in the paper published in the *Phil. Trans.* for 1878 were so nearly represented by a straight line.

FELLOWSHIPS AT OWENS COLLEGE, MANCHESTER

A SCHEME of Science and Literature Fellowships, modelled very closely after the pattern of the Fellowship Scheme of the Johns Hopkins University, Baltimore, has been organised in Owens College, Manchester. The Council propose, early in October next, to appoint to five Fellowships on the terms and conditions following:—1. The appointment will be made by the Council, after receiving a report from the Senate, not on the results of examination, but after consideration of documentary or other evidence furnished to them. 2. Application by persons desiring to hold these fellowships must be made, in writing, on or before October 1. In his application the candidate should indicate the course of his previous reading and study, and his general purposes with reference to future work. 3. The candidate must give evidence of having received a sound and systematic education either in literature or in science, such as the possession of a degree of an English University, or a certificate from the authorities of an English School of Medicine or Science, of good repute, showing that he has passed through his curriculum with distinction, or, in default thereof, such other evidence as shall be satisfactory to the Council that he is qualified to prosecute some special study or investigation in the manner indicated in § 6. Finally, he should produce a satisfactory testimonial of character and conduct, and should give the names of not more than three persons from whom further information may be sought. 4. In the award of the Fellowships regard will be had to the pecuniary circumstances of the candidates. 5. The value of each Fellowship will be 100*l.* for the academical year 1881-82. In case of resignation or other withdrawal from the Fellowship, payment will be made for the time during which the Fellowship may have been actually held. 6. Every holder of a Fellowship will be expected to devote his time to the prosecution of some special study, with the approval of the Council after receiving a report from the Senate; and before the close of the year to give evidence of progress by the preparation of a thesis, the delivery of a lecture, the completion of some research, or in some other method. He will study under the direction of the Professor of the subject in which he is appointed, and will be required to pay such fees as the Council shall in each case determine. 7. He may be called on by the Council, after report from the Senate, to render some service to the College, either as an occasional examiner or by giving instruction in lectures or otherwise, to students in the College—provided always that he shall not, during his tenure of the Fellowship, hold any regular or salaried post as Assistant Lecturer or Demonstrator in the College—but he may not engage in teaching elsewhere. 8. He must reside in Manchester during the academical year. 9. He may be re-appointed at the end of the Session for a second and, in like manner, for a third year. 10. Candidates are invited to apply for appointment in any one of the following nine departments:—(1) Classics; (2) English Language and Literature; (3) History; (4) Philosophy; (5) Pure Mathematics; (6) Applied Mathematics (including Engineering); (7) Physics; (8) Chemistry; (9) Biology (including Physiology)

SOCIETIES AND ACADEMIES

LONDON

Royal Society, June 16.—"On Stratified Discharges. VI. Shadows of Striæ," by William Spottiswoode, P.R.S., and J. Fletcher Moulton, F.R.S.

One of the most interesting questions connected with the subject of stratified discharges is this: What is the physical, as distinguished from the electrical, nature of the striæ themselves? Are they, in fact, to be regarded as aggregations of matter possessing greater density than the gas present in the dark spaces, or are they to be considered as indicating merely special local electrical conditions? The fact of their having a definite configuration, especially on the side which is turned towards the negative terminal of the tube, that of their temperature being higher than that of the dark spaces, the manner in which they are affected by solid bodies, and other considerations, all tend to give support to the view that the striæ are loci of greater density than the dark spaces. Still it can hardly be said that as yet any experimental proof of this has been given sufficiently decisive to decide the question conclusively. And it is in the hope of contributing something towards the solution of this question that the following experiments are submitted to the notice of the Royal Society.

The two terminals of a Holtz machine were connected in the usual way with the two terminals of the tube, so as to produce a stratified discharge. A narrow strip of tin-foil, or a wire, was stretched along the tube opposite the column of striæ. The positive terminal of a second Holtz machine (in practice we used for this purpose a Töppler machine) was connected with the tin-foil, and the negative terminal with one (either) terminal of the tube. An air-spark, or interval across which sparks could pass, was interposed in the part of the circuit between the machine and the tin-foil. The effect of this arrangement was this: In the interval between two sparks the tin-foil and tube became charged like a Leyden jar; the tin-foil being the outer coating, charged positively, and the gas inside serving as the inner coating, charged negatively. When the spark passed across the interval mentioned above, the jar (*i.e.* the tube) became discharged, and the electricity previously held bound on the two coatings was set free.

When the first (say the "internal") machine was not working, or when it was disconnected, *i.e.*, when no regular discharge was passing through the tube, then, whenever a spark passed at the second (or "external") machine, a negative discharge with its accompanying Crookes' radiation took place from the inside of the tube next the tin-foil, and the opposite side of the tube became covered with a sheet of green phosphorescence (the tube being of German glass).

When, however, other things remaining as before, a discharge from the internal machine was sent through the tube, and a good stratified column was produced, it was found that the green phosphorescence was entirely cut off from the parts of the tube opposite to the striæ, while on the parts opposite to the dark spaces it remained, in the form of phosphorescent rings, as brilliant as before. The experiment was repeated with various tubes with various degrees of strength of current, and with various densities of gas (produced by heating a chamber of potash in connection with the tube). It may be added that when, as is sometimes the case, through greater exhaustion, the striæ became feebler in illumination and less compact in appearance, the shadows cast by them lost proportionally in sharpness of definition and in completeness of extinction of the phosphorescent light.

The brilliancy and definition of the phosphorescent rings may be increased by inserting a small Leyden jar in the circuit, care being taken that the jar shall discharge itself completely each time. If this is not the case the main discharge is followed by

subsidiary discharges, which tend to blur the effect. The angle of dispersion may be increased, or rather supplemented, by placing more than one strip on the tube, distant from one another by an angle of 90° or 120°. By this means the rings may be made to comprise the entire circumference of the tube.

It thus appears that the striæ are competent to cast shadows in the radiant showers issuing from the inside of the tube adjacent to the tin-foil, which part acts as a negative terminal. Many experiments have contributed to show that these radiant showers, although accompaniments of the discharge, are not carriers of the discharge; and that, having once issued from their source, they continue their own course irrespective of that of the discharge proper. They are in fact material showers, and, although not improbably charged with electricity, yet their ulterior course does not appear to depend on their electrical condition. Under these circumstances the simplest explanation appears to be that they have been arrested by a material obstacle, and consequently the phenomena above described may be considered as furnishing an experimental proof that the striæ represent local aggregations of matter, and not merely special electrical conditions of the gas.

June 16.—"On Stratified Discharges. VII. Multiple Radiations from the Negative Terminal." By William Spottiswoode, P.R.S., and J. Fletcher Moulton, F.R.S.

On examining the image of a negative terminal as traced out in tubes of great exhaustion, by the phosphorescence due to Crookes' radiations, we have often noticed that the image was not a simple figure, but that more than one outline of the contour of the terminal might be traced. From the fact of the double contour having been first remarked when the terminal was of a conical form, it was at first supposed that the second image might be due to internal reflection, or to some property appertaining to the edge of the cone. But this supposition led to no satisfactory explanation of the phenomenon.

It was however thought that, inasmuch as the two images implied different systems of radiation, a magnet suitably disposed might affect them in different degrees, and thereby throw some light on their origin. For this purpose we used a large electromagnet with its coils so coupled up as to give the two poles similar polarity. By bringing the two poles together, inclined at a moderate angle, a single pole and a field of great magnetic strength was produced.

The tube was then placed in the plane containing the axis of the two poles, and in the direction of a line bisecting their directions. The tubes first used were of great exhaustion, and were placed sometimes with the positive, sometimes with the negative terminal towards the magnet. When the tube was placed in a comparatively weak part of the field the two images of the cone were seen in their usual positions relatively to each other, except that they were slightly more separated. But as the tube was brought gradually into a stronger part of the field the two images became further separated, and by degrees a third, a fourth, and even more images were brought out on the side of the tube. In one tube of very high exhaustion, for which we are indebted to Mr. Crookes, as many as eight images became visible.

We have then, as an experimental fact, a series of images, each formed by a system of rays issuing from the surface of the negative terminal. The images being distinct, the system of rays must be distinct also. Now, as it seems hardly possible to imagine that, from every point of a surface, there can issue at one and the same instant of time a variety of systems of radiations, each system ranging over a finite angular distance, and each differently directed in space, we are driven to the conclusion that these radiations must have issued successively and not simultaneously from the terminal. In other words, the various images are formed in succession. Now, the entire series of images are present whenever a discharge passes through the tube; and when a "continuous" discharge (such as that from a Holtz machine) is passing, they are all as steady and as persistent as are any other features of the discharge. From this it follows that the radiations are not a continuous phenomenon, but that they are composed of a recurrent series of discharges, each having its own angular range, and its own direction in space; and as the electricity, which is the motive power, and the metallic terminal, which is the directing machinery, are the same in kind for each image, we are led to the conclusion that the positions of the images are determined by the force with which the radiations are projected. In fact, we understand that the various images are due to a succession of discrete discharges of successively diminishing strength.

The phenomenon of multiple images of the negative terminal as explained above has an important bearing on the nature of electrical discharges in vacuum tubes. For, if the phosphorising radiation consists of a recurring series of discrete discharges, the radiation in each series, and *à fortiori* the radiation as a whole, is discontinuous; and consequently the electrical discharge, to which it is due, must itself be discontinuous or "disruptive." We appear, therefore, in these phenomena to have an experimental proof, independent of and in addition to those adduced by Mr. De La Rue and others, of a fundamental point in the theory of these discharges, namely, their disruptive character.

Geological Society, June 8.—R. Etheridge, F.R.S., president, in the chair.—The meeting was made a special general meeting for the election of a Member of the Council in the room of the late Sir P. de Malpas Grey-Egerton, Bart., M.P., F.R.S., F.G.S.—The President announced that the late Sir Philip Egerton had bequeathed to the Society all the original drawings made from specimens in his collection for the illustration of Prof. Agassiz's works on Fossil Fishes. The Society had long possessed the drawings made for the same purpose from the Earl of Ellesmere's collection, and some years ago the Earl of Enniskillen presented those which had been prepared from specimens in his possession. Sir Philip Egerton's kind bequest would complete this interesting series.—Sir John Lubbock, Bart., M.P., F.R.S., was elected a new Member of Council. Messrs. Grenville A. J. Cole and J. L. Roberti were elected Fellows, and Il Commendatore Quintino Sella of Rome a Foreign Member of the Society.—The following communications were read:—The reptile-fauna of the Gosau formation, preserved in the Geological Museum of the University of Vienna, by Prof. H. G. Seeley, F.R.S., with a note on the geological horizon of the fossils, by Edward Suess, F.M.G.S. The collection of reptiles described in this paper was obtained at Neue Welt, near Wiener Neustadt, by tunnelling into the freshwater deposits which there yield coal. A part of the collection was described by Dr. Bunzel in 1871; but the author's interpretation of the fossils rendered a re-examination of the whole collection necessary. All the species hitherto discovered are new, and, with the exception of those referred to *Crocodilus*, *Megalosaurus*, *Ornithochirus*, and *Emys*, are placed in new genera. Nearly all the bones are more or less imperfect. The *Iguanodon Suessii*, of Bunzel, was referred to a new genus, *Mochlodon*, characterised by the straight anterior end of the ramus of the lower jaw and by the vertical bar in the middle of the teeth of the lower jaw. There appear to be two teeth in the ramus. The tooth referred to the upper jaw has several uniform parallel vertical bars. A small parietal bone, referred by Bunzel to a lizard, is considered by the author to belong probably to the same species, and, with some doubt, he associated with it the articular end of a small scapula. Bunzel's *Struthiosaurus Austriacus* was re-described by the author, who indicated that the bones of the base of the brain-case, regarded by Bunzel as the quadrate bones, really belong to the occipital region, which necessitates a different interpretation. The foramina along the base of the skull were also described as presenting one of the characteristics of the Dinosaurian order. The base of the skull of *Acanthopholis horridus* was described to show its relation to the above type, with the view of demonstrating its Scelidosaurian affinities. The greater part of the remains were referred by the author to a new genus, *Crateomus*; some of these had been figured by Bunzel as "Crocodili ambigui," and others as belonging to *Scelidosaurus*, and to a new Lacertilian genus, *Danubiosaurus*. To *Crateomus* he referred mandibles, teeth, vertebræ from all parts of the column except the sacrum, dermal armour, and the chief bones of the limbs. Two species were distinguished, *C. Paulowitschii* and *C. lepidophorus*. The former, which is much the larger, was named in honour of M. Paulowitsch, who voluntarily superintended the work at the Neue Welt. The author stated that he regarded these animals as carnivorous, and that, unlike the typical Wealden Dinosaurs, they were not kangaroo-like in habit, but had strongly developed fore limbs, as indicated in the proposed generic name. Two teeth belonging to *Megalosaurus* were described as representing a new species, *M. Pannoniensis*, characterised by the crown being shorter and broader than in previously described forms. A fragment, regarded by Bunzel as the thoracic rib of a lizard, was interpreted as the distal end of the femur of a Dinosaur, and named *Ornithomerus gracilis*. The lower jaw, described by Bunzel as *Crocodilus carcharidens*, of which a maxillary bone also occurs, was made the basis of a new genus, *Doratodon*,

probably Dinosaurian, judging from the lateral position of the apertures of the skull and the characters of the teeth. The genus *Rhadinosaurus* was founded upon the humerus and femur, the latter having been regarded by Bunzel as the dorsal rib of a crocodile; the species was named *R. alcimus*. *Oligosaurus adelus* was described as presenting Lacertilian characters in combination with some Dinosaurian peculiarities. The remains include the humerus, femur and scapula, and two vertebræ, which were regarded by Bunzel as fœtal vertebræ of a Dinosaur. The genus *Hoplosaurus* was founded on some vertebræ, fragments of limb-bones, and dermal armour; it shows, with distinctive peculiarities, a certain resemblance to *Hylæosaurus*. A procœlian crocodile was represented by many parts of the skeleton; some figured by Bunzel as Lacertilian, others as Crocodilian. It is remarkable for having a buttress supporting the transverse process in the lumbar region. The author calls it *Crocovilus proavus*. The specimen figured by Bunzel as the ilium of his *Danubiosaurus anceps*, was stated by the author to be a costal plate of a large Chelonian, in which, apparently, the margins of these plates remained separate through life. Skull bones, believed to belong to the same animal, are strongly sculptured; the author named the species *Pleuropeltus lissus*. Three or four species of Emydians were said to be indicated by isolated plates, the largest of which was named *Emys Neumayri*. The only specimen referable with certainty to a lizard is a small vertebra of elongated form, regarded as indicating a new genus and species, named *Spondylosaurus gracilis*. Of Pterodactyls there are but few remains; but these certainly represent two genera. The author only describes one species, to which he gives the name of *Ornithochirus Bunzeli*. There are, in all, probably ten genera of Dinosaurs, and five genera of other groups, making fifteen in all. The paper was supplemented by a note by Prof. Suess on the geological relations of the beds at Wiener Neu-stadt to those of the Gosau Valley, in which he comes to the conclusion that they are older than the true Turonian deposits, and especially older than the zone of *Hippurites cornu vaccinum*.—On the basement-beds of the Cambrian in Anglesey, by Prof. T. McKenny Hughes, M.A., F.G.S. In this paper the author first pointed out that there was in Anglesey:—(1) An upper slaty group, in which he had fixed two live zones, which showed that the series belonged to the Silurian (Sedgwick's classification), and (2) a lower group of slates and sandstones in which Arenig fossils had been found in several localities, and Tremadoc had been less clearly recognised, while by the correction of the determination of a species of *Orthis*, there was now a suspicion of even Menevian forms. These all rested upon the basement-beds of the Cambrian, of which the paper chiefly treated. They were made up of conglomerates, grits, and sandstones, with Annelids and Fucoids. The basement-beds varied in thickness and character according to the drift of currents along the pre-Cambrian shore and the material of the underlying rocks. Near Penlon, where they rested on a quartz-felspar rock, they consisted chiefly of a quartz-grit and conglomerate, almost exactly like that of Twt Hill. Near Llanerchymedd, where there was a mass of greenish schistose rock succeeding the Dimetian, the Cambrian basement-bed contained a large number of fragments of that rock, certain bands being chiefly composed of it. Near Bryngwallen, where the underlying Archæan consisted of gneissic rocks, the Cambrian basement-beds were made up of quartz conglomerate. Tracing it still further to the south-west he found bosses of conglomerate among the sand dunes of Cymmeran Bay, full of fragments of green schistose rock like that of Bangor, and telling of the further development of Pebidian at the south-west end of the Anglesey axis. In several localities these conglomerates were associated with and passed into fossiliferous grits and sandstones. He exhibited slices of the more important rocks, which he showed confirmed the results arrived at from other evidence. He pointed out that the observations now made confirmed the views he had expressed on a former occasion with regard to the basement-beds of the Cambrian between Caernarvon and Bangor, where the deposits which rested upon the granitoid rocks of Twt Hill were either a kind of arkose or chiefly composed of quartz with a few pieces of mica-schist and jasper; but as he followed them a few miles to the north-east he found that the quartz had got pounded into smaller grains, and the larger pebbles were chiefly of felsite, which here formed the shore, while further towards Bangor fragments of the still higher Bangor volcanic series helped to make up the Cambrian shingle-beach.—Description and correlation of the Bournemouth beds. Part II. Lower or freshwater series, by J. S. Gardner, F.G.S. This was in continuation of a former paper by the author (*Q. J. G. S.* vol. xxxv. p. 209). The beds described are exposed east and west of Bournemouth and near Poole harbour, over a distance of about four miles. The author referred them to the Middle Bagshot, and stated that they are distinguished from the Lower Bagshot by the absence of the extensive pipe-clay deposits and the presence of brick-earths, and from the overlying beds by the absence of flints. They reach their extreme limit in the western area of the London basin, and are represented by the lignitic beds 19-24 of Prof. Prestwich's section. Lignites can be traced partly across the bay. The cliffs present an oblique section across a delta divisible roughly into four masses, one of which, from its confused bedding and want of fossils, is supposed to have been formed by the silting up of the main channel. The total thickness of the series was estimated at 600 to 700 feet. The inferences drawn by the author were as follows:—(1) From the beds cut through showing a steep side to the west, that the river flowed from that direction; (2) from the absence of boulders or coarse sediment, that the area was flat; (3) from the absence of lignite, that there were catchment basins; (4) from the absence of flint, and the quartzose nature of the beds, that no chalk escarpments were cut through, and that the deposits came from a granitic area; and (5) from the presence of wood bored by *Teredo* that the beds belong to the lower part of the river in proximity to tidal water. The flora was stated to be confined to local patches of clay. Those at the western end of the section are very rich, and distinguished from the rest by absence of palms and rarity of ferns. The beds near Bournemouth are still richer and very distinct; those east of Bournemouth are characterised by *Eucalypti*, Aroids, and *Araucariæ*; and those at the western end of the section by abundant Polypodiaceæ. It is remarkable that nearly every patch contains a flora almost peculiar to it; but the flora as a whole seems to pass upward to the Oligocene, but not down to the Lower Bagshot.

Sanitary Institute of Great Britain, June 21.—Dr. A. Carpenter in the chair.—A paper was read by Prof. W. H. Corfield, M.A., M.D., on the present state of the sewage question. In the discussion which followed Mr. W. C. Sillar, Mr. E. F. Bailey Denton, Mr. Douglas Onslow, Mr. R. W. P. Birch, Mr. G. B. Jerram, and Mr. Wilson Grindle took part. The Chairman made a few remarks relative to the successful working of the sewage farm at Croydon, and Prof. Corfield replied briefly to some of the points raised in the discussion.

INHERITANCE

THE tendency in any new character or modification to reappear in the offspring at the same age at which it first appeared in the parents or in one of the parents, is of so much importance in reference to the diversified characters proper to the larvæ of many animals at successive ages, that almost any fresh instance is worth putting on record. I have given many such instances under the term of "inheritance at corresponding ages." No doubt the fact of variations being sometimes inherited at an earlier age than that at which they first appeared—a form of inheritance which has been called by some naturalists "accelerated inheritance"—is almost equally important, for, as was shown in the first edition of the "Origin of Species," all the leading facts of embryology can be explained by these two forms of inheritance, combined with the fact of many variations arising at a somewhat late stage of life. A good instance of inheritance at a corresponding age has lately been communicated to me by Mr. J. P. Bishop of Perry, Wyoming, N.Y., United States:—The hair of a gentleman of American birth (whose name I suppress) began to turn grey when he was twenty years old, and in the course of four or five years became perfectly white. He is now seventy-five years old, and retains plenty of hair on his head. His wife had dark hair, which, at the age of seventy, was only sprinkled with grey. They had four children, all daughters, now grown to womanhood. The eldest daughter began to turn grey at about twenty, and her hair at thirty was perfectly white. A second daughter began to be grey at the same age, and her hair is now almost white. The two remaining daughters have not inherited the peculiarity. Two of the maternal aunts of the father of these children "began to turn grey at an early age, so that by middle life their hair was white." Hence the gentleman in question spoke of the change of colour of his own hair as "a family peculiarity."

Mr. Bishop has also given me a case of inheritance of another kind, namely, of a peculiarity which arose, as it appears, from an injury, accompanied by a diseased state of the part. This latter fact seems to be an important element in all such cases, as I have elsewhere endeavoured to show. A gentleman, when a boy, had the skin of both thumbs badly cracked from exposure to cold, combined with some skin disease. His thumbs swelled greatly, and remained in this state for a long time. When they healed they were misshapen, and the nails ever afterwards were singularly narrow, short, and thick. This gentleman had four children, of whom the eldest, Sarah, had both her thumbs and nails like her father's; the third child, also a daughter, had one thumb similarly deformed. The two other children, a boy and girl, were normal. The daughter, Sarah, had four children, of whom the eldest and the third, both daughters, had their two thumbs deformed; the other two children, a boy and girl, were normal. The great-grandchildren of this gentleman were all normal. Mr. Bishop believes that the old gentleman was correct in attributing the state of his thumbs to cold aided by skin disease, as he positively asserted that his thumbs were not originally misshapen, and there was no record of any previous inherited tendency of the kind in his family. He had six brothers and sisters, who lived to have families, some of them very large families, and in none was there any trace of deformity in their thumbs.

Several more or less closely analogous cases have been recorded; but until within a recent period every one naturally felt much doubt whether the effects of a mutilation or injury were ever really inherited, as accidental coincidences would almost certainly occasionally occur. The subject, however, now wears a totally different aspect, since Dr. Brown-Séquard's famous experiments proving that guinea-pigs of the next generation were affected by operations on certain nerves. Mr. Eugène Dupuy of San Francisco, California, has likewise found, as he informs me, that with these animals "lesions of nerve-trunks are almost invariably transmitted." For instance, "the effects of sections of the cervical sympathetic on the eyes are reproduced in the young, also epilepsy (as described by my eminent friend and master, Dr. Brown-Séquard) when induced by lesions of the sciatic nerve." Mr. Dupuy has communicated to me a still more remarkable case of the transmitted effects on the brain from an injury to a nerve; but I do not feel at liberty to give this case, as Mr. Dupuy intends to pursue his researches, and will, as I hope, publish the results.

July 13 CHARLES DARWIN

VOLCANOES

Volcanoes: what they are, and what they Teach. By John W. Judd, F.R.S., Professor of Geology in the Royal School of Mines. (London: C. Kegan Paul and Co., 1881.)

ONE of the fathers of vulcanology in this country was the late Mr. Poulett Scrope, in whose well-known treatise on Volcanoes, the subject of their cause and effect was for the first time discussed from a thoroughly philosophical standpoint. A great traveller and investigator himself, he strove to imbue younger geologists with his spirit, and when he became too old and infirm to undertake travel and research in distant countries, he directed some chosen disciples to prosecute his favourite lines of thought. Prof. Judd was one of these, and upon him has assuredly fallen the mantle, and a portion of the spirit of his master. His able papers on the study of volcanoes, contributed to the *Geological Magazine*, are well known to every vulcanologist. He has travelled much; he makes good use of both pen and pencil, and he is an accurate observer. We are glad that he has condensed his reading and research into a work, which becomes so widely distributed, both at home and abroad, as the volumes of the International Scientific Series invariably do.

Before entering more minutely into a discussion of the work, we would venture to say that among its few defects, that which strikes us most prominently is an insufficiency of logical sequence and method. The facts are multitudinous; carefully selected, but not carefully arranged. They require to be grouped; to be classified, and each set of facts to be set in apposition to the generalisation which they tend to prove. It is indeed a useful mental discipline for the reader to do this for himself, but unless he starts with some knowledge of the subject, and as the

possessor of a thoroughly methodical habit of mind, he can scarcely hope to arrange all the facts as they should be.

After an introductory chapter on the general nature of the inquiry instituted in the succeeding chapters, the author discusses "the nature of volcanic action." To illustrate this he takes the case of the ever-active volcano Stromboli, first examined scientifically by Spallanzani in 1788, and by Mr. Judd in 1874. It is a conical mountain rising 3090 feet above the sea, but the shore slopes to a depth of nearly 600 fathoms, hence the real height of the mountain from the bottom of the ocean exceeds 6000 feet. On the upper side of the crater a spot exists from which it is possible to look down upon the floor of the crater, and here may be seen apertures in which three classes of action take place. From some high-pressure steam is emitted in loud puffs; from others masses of molten lava well out; and in the third kind, a semi-liquid substance may be seen heaving up and down. Sometimes it rises as a kind of scum, swollen by the steam beneath it, and at last a gigantic bubble of molten lava filled with steam appears, and bursts; the imprisoned steam then escapes, carrying with it masses of the bubble high into the air. The author considers that all volcanic phenomena depend on these same conditions: (*a*) cracks or apertures forming communication between the surface and the interior of the earth; (*b*) highly heated matter beneath the surface; and (*c*) imprisoned water.

Animadverting on the common delusion that a volcano is a burning mountain, and that sulphur is the combustible, it is shown that sulphur is the result and not the cause of volcanic action. Common constituents of volcanic action are sulphurous acid and sulphuretted hydrogen, and when these come into contact, according to the author, "water and sulphuric acid are formed and a certain quantity of sulphur is set free." It should be understood however that if the gases are at all dry, as they sometimes are in the Solfataras of Krisuvik and elsewhere, water and sulphur are the sole products of the decomposition, while if moist, sulphur, water, and pentathionic acid are the first result.

If we examine the history of Vesuvius and other volcanic centres which have been known from a remote antiquity, we are led to the following conclusions, as regards the frequency of outbursts:—"(1) A long period of quiescence is generally followed by an eruption which is either of long duration, or of great violence. (2) A long-continued, or very violent eruption is usually followed by a prolonged period of repose. (3) Feeble and short eruptions usually succeed one another at brief intervals. (4) As a general rule, the violence of a great eruption is inversely proportional to its duration."

In the third chapter the author describes the products of volcanic action. In the account of Vulcano he has omitted to mention the very remarkable substance lately analysed by Prof. Cossa of Turin, which contains no fewer than seven non-metals and eight metals, combined in the following forms:—Arsenious sulphide, selenium sulphide, boric acid, ammonium chloride, lithium sulphate, thallium alum, cæsium alum, rubidium alum, and potassium alum. Bunsen's important division of all lavas into "acid lavas" and "basic lavas" is accepted, and the author admits an intermediate lava which contains from 55 to 66 per cent. of silica. He divides lavas further into five great groups: the Rhyolites, Trachytes, Andesites, Phonolites, and Basalts; the first being *acid*, the last *basic*, and the three others intermediate. An interesting account (illustrated by the frontispiece) is given of the microscopic examination of thin sections of rock, and the practicability of tracing by this means the passage from a glassy to a crystalline lava. It is shown that volcanic rocks having precisely the same chemical composition differ considerably in texture according as they are cooled slowly or rapidly. Thus gabbro, basalt, and trachyte are respectively the crystalline, lava, and glassy forms of the same substance. Some interesting details are given of the liquid cavities found in certain crystals, and of their contents.

In the fourth chapter the distribution of materials ejected from volcanic vents is discussed. In the account of "Pele's Hair"—the long threads of lava blown out by high-pressure steam in Hawaii—the reader may be misled. The author speaks of it as "filamentous volcanic glass," and in the passage preceding it (p. 71) he is evidently discussing "glassy lavas" and "pumice," which have been ranged among the acid lavas. But on p. 94 the same lava of Kilauea is spoken of as a "basic lava," although before described as a "molten glass," and presumably acid in character, that is, containing from 66 to 80 per cent. of silica. But basalt is a basic lava, and by rapid cooling it may become a perfect glass, hence we can understand how Pele's Hair may be described as "filamentous glass," without belonging to the class of acid lavas.

In the following chapter an extremely interesting account of the dissection of volcanoes by denudation is given, and the subject is illustrated by some striking examples, among which we may specially mention the plan of the volcano of Mull in the Inner Hebrides. In a past geological period this volcano was probably as large as Etna. The Island of Skye is the basal wreck of another volcano of Tertiary times. In the account of the formation of mineral veins the author has not alluded to Bunsen's surmise that the metallic copper found in the palagonite tuff of the Faroe Islands was reduced by volcanic hydrogen from the chloride.

The sixth chapter treats of the parasitic cones which appear upon the flanks of great volcanoes, and herein we notice one or two errors. Thus on p. 162 we read, "Among the hundreds of parasitic cones which stud the flanks of Etna, there are some which are nearly 800 feet in height." There are however less than a hundred cones worthy of the name, the rest are mere monticules, and of these we believe there are over six hundred. Among the larger cones Monte Minardo is the largest, and it is 750 feet in height, but has undoubtedly been much higher. In Fig. 63, p. 163, the outline of Etna, *as seen from the Val del Bove*, is wrongly described. The picture represents Etna as seen from Bronte, the opposite side of the mountain to the Val del Bove. It is taken from von Waltershausen's "Atlas des Ætna," and appears in Mr. Scrope's book on Volcanoes, in which it is also wrongly described. Occasionally we meet with hasty writing, particularly when the author is firmly convinced of his statement. Such small defects are easily remedied in the second edition. The following is an example of what we mean:

"That volcanoes are thus built up along lines of fissure in the earth's crust, we have the most convincing proofs. Not only have such fissures been seen in actual course of formation at Vesuvius, Etna, and other active volcanoes, but a study of the volcanoes dissected by denudation affords the most convincing evidence of the same fact. The remarkable linear arrangement of volcanoes, which is conspicuous to the most superficial observer, is a very striking evidence of the same fact." A slight looseness of expression is also apparent when the author speaks of carbonic acid as a *poisonous gas*, the fact being that the gas produces suffocation by spasmodically closing the glottis and without entering the lungs at all. On the other hand, carbonic oxide, which has a direct and baneful action on the organism, may truly be described as a poisonous gas.

In the account of Geysers the author, after stating that many attempts have been made to explain the mechanism by which the intermittent action of geysers is produced, remarks that probably no "such explanation will cover all the varied phenomena exhibited by them." Herein he does not even allude to Bunsen's classical experiments on the action of geysers, which are generally accepted as furnishing conclusive proofs of the mechanics of these intermittent springs.

A highly-instructive chapter discusses the number and distribution of volcanoes. In the second edition the map inserted at the beginning of Mr. Scrope's book might with advantage be introduced.

Concluding chapters discuss the information furnished by volcanoes concerning the interior of the earth, and the attempts made to explain the causes of volcanic action. In regard to this latter matter we are left as much in the dark as ever, and authors usually content themselves with stating the various hypotheses which have been proposed, leaving the reader to select that which he considers the most rational.

Prof. Judd's work is very instructive, and it will excite intense interest in the minds of many readers. Laid down upon the lines of Mr. Scrope's book, it is less methodical, less philosophical, and to most people more readable. A few things seem to us to be wanting, but probably the author has good reasons for their omission. Particularly we notice the absence of references to the labours of such men as Bunsen, von Waltershausen, Johnstrup, von Lasaulx, Steenstrup, Elie de Beaumont, and Tacchini. Iceland, the most marvellous country in the world from the volcanic point of view, is scarcely alluded to. And, as we said above, it seems to us that we require some *νοῦς* to arrange and put in order the countless *ὁμοιομέρειαι* that are scattered throughout the pages. But even without this we cannot read the book attentively without feeling that we have acquired a great mass of information concerning phenomena which have occupied the attention of wise men from the earliest times.

G. F. RODWELL

THE FIGURE OF THE EARTH

The Figure of the Earth: an Introduction to Geodesy. By Mansfield Merriman. (New York, 1881.)

THE author of this volume has already made his name known to us as the writer of an excellent treatise on the Method of Least Squares. The book before us presents to the reader, who is supposed to have some little knowledge of Algebra and Geometry, an explanatory and historical sketch of the labours of geodesists from the earliest days. We read in Chapter I. that Anaximander—a speculator in Geometry, Astronomy, and other sciences—concluded, from some reasons best known to himself, that the earth was a cylinder whose height is three times its diameter. There must have been some good reason for this idea, for we are told that Anaxagoras held the same. And it is scarcely to be wondered at that Plato originated some views of his own in the matter.

Passing to comparatively modern times we have a detailed account of the measurement of a degree (in 1766-68) by Mason and Dixon along the boundary line between the states of Maryland and Delaware. This measure gave 3947 miles as the radius of our supposed sphere.

Then the Franco-Peruvian expedition—*circa* 1736—of the Academicians MM. Bouguer and Lacondamine is briefly referred to (and here there is a misprint in the length of the base-line at Cotchesqui, which was 6274 toises in length), their labours giving 3936 miles as the radius. Henceforth the earth, abandoning its claims to sphericity, and not escaping a temporary imputation of being egg-shaped, settles down into an oblate spheroid—the figure generated by the revolution of an ellipse round its lesser axis.

Chapter II. treats of the method of determining the excentricity of this spheroid. As one measured arc will determine the radius of the spherical earth, so two measured arcs determine the radii of the spheroidal earth, that is, if the two arcs differ considerably in latitude. The actual excentricity is then calculated from the arc measured in Peru and that measured in Lapland. Then, further, taking the arc measured in France and combining these three in pairs, three quite different values of the excentricity are obtained. Here enters a discord not yet resolved; and in fact all modern measurements show that the earth is not a true spheroid, for, combining the arcs in pairs, all kinds of values of the excentricity present themselves. Then we fall back on the method of least squares, and grouping all the measurements into a unique calculation, we get a unique value of the excentricity, which may, with some show of reason, be called the most probable value. A specimen of this mode of calculation applied to pendulum observations is given at page 52; and it may be noted in passing that the calculation would have been made both neater and simpler by writing $S + 39$ instead of S. By inadvertence it is stated at page 54 that pendulum observations give 1–288·5 as the earth's ellipticity, and again at page 64, 1–289 is given as the result of the same observations. But these are the ellipticities that were obtained previous to the very extensive pendulum work recently completed by General Walker in India. When these modern observations are taken into account the 1–289 is changed to 1–292 or 1–293.

The earth then being no true spheroid, an attempt, described in Chapter III., is made to ascertain whether it is an ellipsoid with three unequal axes. Here but little better success is met with, and failing to establish for itself any fair name, the earth, like other pretenders, takes shelter under hard words, and in the concluding chapter of the book calls itself a geoid. Here we are safe and

beyond controversy, for your geoid makes no pretensions except to irregularity.

The surface of the geoid is in fact at every point perpendicular to the direction of gravity there. Thus the surface of the (unagitated) sea is a geoid, the surface of all lakes are portions of geoidal surfaces, nearly but not exactly parallel to that of the sea. That particular geoidal surface which represents the figure of the earth is the sea surface, which indeed is an old enough idea with a new name.

The work may be characterised as a fairly successful attempt to combine the advantages of a scientific and a popular treatment of its subject. It does not claim originality, and the mechanical theory of the earth's figure is not touched on.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Special Solar Heat-Radiations and their Earth-felt Effects

I REGRET if, by the words "lagging behind" in my paper to NATURE, vol. xxiv. p. 150, I have inadvertently misrepresented the views of Prof. Piazzi Smyth. Had his paper been only recently published, I might have been able to plead ignorance of its contents, but it is one which was published in 1869, and which I have read several times in the belief that it contains not only the first, but likewise the most complete contribution to this branch of knowledge.

Having made this confession, let me now in a very words endeavour to render clear that which I intended to say.

The hypothesis advocated in the lectures to which Prof. Smyth alludes was that which represents the sun as most powerful when it has most spots on its surface. Nevertheless if we take the observations of Prof. Smyth, of Mr. Stone, and of Dr. Köppen, and bring them together, we are led to think that perhaps on the whole we have highest temperatures about those times when there are fewest spots on the sun's surface. I then endeavoured to show that such an experience was nevertheless not inconsistent with the hypothesis of increased solar heat during times of most sun-spots.

Again, if we take rainfall, while we find that perhaps on the whole there is most rain during times of maximum sun-spots, yet there are certain stations which form an exception to this rule. Nor is this to be wondered at if we reflect that the direction, as well as the intensity, of the earth's convection currents must be affected by solar variability, and bear in mind that local causes have a very powerful influence upon rainfall. Now this last remark applies to temperature as well. I should therefore be prepared to hold, *simply as a working hypothesis*—

1. That, on the whole, the temperature on land may be less at times of maximum than at times of minimum sun-spots.

2. That, on the whole, the rainfall on land may be greater at times of maximum than at times of minimum sun-spots.

3. That while a period of temperature and one of rainfall coinciding with the sun-spot period will probably be found at most stations, nevertheless in individual localities the turning-points of these periods may vary considerably from the rule laid down in 1 and 2.

4. That the above order of phenomena is not inconsistent with the hypothesis that the sun is most powerful when there are most spots on its surface.

In conclusion permit me cordially to assent to the remarks of Prof. Smyth about the possibility of rapid outbreaks of solar heat being responded to by the earth; it may be only a few hours afterwards. His Madeira observations are of great interest to those who, like ourselves, believe that the bond between the sun and the earth is more intimate and sympathetic and less formal in its nature than that which the older generations of astronomers have been accustomed to imagine.

14, Queen's Road, Bayswater BALFOUR STEWART

How to Prevent Drowning

I OBSERVE several letters in NATURE, vol. xxiv. pp. 101 and 126, on floating as a means of preventing drowning, but I do not think the last word is yet said on this subject. I fully agree with Dr. Dudgeon that no rules for preventing drowning are of any practical value, and also with Mr. Hill and Dr. Dudgeon that those who can float are the rare exceptions. According to my observation not one in ten, in fact I might say hardly one in 100 even, of good swimmers can float in fresh water in any useful fashion, *i.e.*, lying motionless on the water and breathing easily. The obvious reason is that the human body in the natural condition, *i.e.*, with the lungs half inflated, is specifically heavier than water. Many persons say they can float, but in most cases they either inflate the lungs and hold the breath, or else they make slight movements of the hands.

But Dr. Dudgeon is wrong in supposing that the exceptions are all fat men. I am myself a case in point. I am slender almost to meagreness, and yet I float easily. From boyhood I have been fond of all athletic sports, and especially I am a practised and expert swimmer. I swim almost as easily as I walk. I float even in fresh water with the utmost ease, and for any length of time, breathing meanwhile naturally. While floating, the whole face, a large area on the chest, a small spot on the knees, and the tips of the toes are above the surface. Breathing causes the body to rise and fall gently, so that the exposed areas of the face and chest increase and diminish alternately.

It is evident therefore that the cases of persons who can really float are of two kinds, viz., (1) Those who are very fat, and (2) slender persons with very small bones and proportionately large lungs. This latter is my case. I never knew a heavy, muscular, large-boned man without excess of fat who could float. Such men make powerful swimmers, but are less easy and graceful in the water than those who are slenderer.

Berkeley, California, June 27 JOSEPH LE CONTE

Optical Phenomenon

I INCLOSE copies of photographs from two negatives (as you may see by looking at the points stereoscopically) of the Cyclopean gallery at Tiryns, for the sake of calling attention to the optical phenomenon shown in it. The gallery is very dark, the only light entering it by the narrow entrance and crevices between the rocks. At the extreme end of the gallery is an opening to the sky large enough to put one's hand through. In the photograph this is shown as a nucleus by a black speck surrounded by bright light, around which appears a dark circle, which again is encircled by a halo as perfectly rendered as one can see that around the moon at times. The dark nucleus is larger in the negative which had the longest exposure (the irregular lights around are only the light falling on the stones from side openings not visible). There was no such phenomenon recognisable to the naked eye.

The exposures were 25 and 15 min. with the full opening of the Ross "portable" lens and a gelatine plate.

Athens, July 3 W. J. STILLMAN

[The photographs quite bear out Mr. Stillman's statements. —ED.]

Implements at Acton

IN reply to the letter of Mr. Worthington G. Smith (NATURE, vol. xxiv. p. 141), the Palæolithic implements at Acton I found in a gravel pit on the hill west of the North London Railway, and from spread gravel which was local. Those I obtained at Hammersmith occurred in gravel raised on a piece of ground (Mr. Butt's) south of Great Church Lane, where building is going on. They consisted of a hollow scraper, drill, &c., which I readily found; but the implements here seem ruder than at Acton, and less easy of detection. I also found implements in gravel raised from the foundations of the neighbouring houses, which had been spread on some newly-made roads south of Shepherd's Bush, between the Uxbridge Road and Addison Road Stations. I see no reason for supposing that the implements here or at Hammersmith occur under different conditions from those at Acton.

I examined carefully, some weeks ago, some extensive heaps of sand and gravel raised on the premises of the Water-works Company on the right across the Hammersmith Suspension-bridge, but found no worked flints. The gravel here may be of more recent deposition.

With regard to the Neolithic implements of Acton, I am interested to hear that Mr. Worthington Smith is familiar with them, and that there are specimens in the Pitt-Rivers Collection. My letter nevertheless will have done good in making their occurrence more generally known.

As regards the quartzite pebble, if more are found on the fields about Acton it will tend to show that they have served the same purpose as those in South-East Devon, and that they have been brought from a region where specimens adapted for missiles would be found in abundance, viz. the south-west coast, as gravel sections and gravel pits were not accessible in Neolithic times, nor would they have proved adequate arsenals. But if the pebble I found at Acton were accidentally derived from the Middlesex gravel (which contains a considerable quantity of Midland Bunter material), it is remarkable that a selection should have been made so well calculated to deceive a Devonshire neolithologist.

July 19 SPENCER GEO. PERCEVAL

Lightning

ABOUT 10 a.m. of the 6th instant two of the labourers on this farm were sitting on the ground (with their backs against a clover haystack and their faces towards the north, having in front of them and on their left a wood) engaged in eating their lunch. It had been raining and thundering for about half an hour, but not heavily, until suddenly—in the words of one of the men—"a flash of lightning came right at us as if it were shot out of a gun." This man had his knife up to his mouth at the time in the act of eating, and he describes his sensation as a feeling of nausea in his throat and chest, and also that both he and his companion felt an actual push against their shoulders, which swayed and shook them to a considerable extent from the direction of the flash. The other man was blinded for about five minutes, and they were both much dazed for some time. Also they both describe having heard a sharp whiz somewhat resembling the quick escape of steam from an escape valve on an engine. For two days after they both suffered from severe headache. A. HALL, JUN.

Filstone Hall, Shoreham, Kent, July 11

THE COMET

IN a paper read to the Paris Academy on the 11th inst., giving further observations on comet *b* 1881, M. Wolf says:—

"The analysis of the light of the comet furnishes data as to the constitution of that body, which it is important to consider before starting any hypothesis as to its nature and mode of evolution.

"I have examined the spectrum of the comet, both with a highly dispersive spectroscope mounted on the Foucault telescope of 0·40 m. aperture, and with a smaller instrument, mounted on the telescope of 1·20m., giving therefore a very large quantity of light. This spectrum is triple: one sees (1) a continuous spectrum, broad, but very pale, visible in all the regions of the comet; (2) a continuous spectrum nearly linear, and very bright, given by the nucleus; (3) the spectrum of three bands, yellow, green, and blue, characteristic of the light of all comets examined hitherto. I have never been able to see the violet band.

"The continuous spectrum of the nucleus indicates the existence of solid or liquid matter, luminous of itself or by reflection. I have suspected in the strip some dark interruptions, especially in the region near D, without being able to determine their position. The presence of these dark lines, demonstrated by Dr. Huggins' photographs, denotes a reflected light, which can be no other than that of the sun.

"The nebulosity which forms the head of the comet gives, besides the continuous pale spectrum, the bright bands of an incandescent compound gas. The researches of M. Hasselberg tend to assimilate these bands to those of a carburet of hydrogen, probably acetylene. Besides these bands one sees throughout the strip formed by the light of the nucleus other protuberances very short, and paler, which seem to indicate, in the hotter and more luminous parts of the comet, an incandescent atmosphere of more complex constitution.

"When the slit of the spectroscope is passed over the comet, starting from the head, one finds the three bands all round the nucleus, at nearly the same distance from all the sides. They disappear in the tail properly so-called, the very pale spectrum of which seems to be continuous. Thus only the nebulosity surrounding the nucleus contains incandescent gases. The light of the tail comes to us from a pulverulent matter, luminous, or simply illuminated. Such are the data of spectroscopy.

"The polariscopic examination of the comet's light completes these first results. I used, as polariscope, a quartz plate perpendicular to the axis, giving the sensible tint, and a double-refracting prism, placed between a collimator and an observing telescope, in place of the prism of a direct-vision spectroscope. The two images of the nucleus and the nebulosity surrounding it are projected, well separate, on the common part of the field formed by the background of the sky; this is the process indicated long ago by M. Prazmowski for eliminating atmospheric polarisation. Under these conditions the nucleus and the nebulosity appear both distinctly polarised in the median plane of the tail, consequently in the plane passing through the sun. Here then, at least in all parts of the nebulosity round the nucleus, we have reflected light coming from the sun, and a non-gaseous matter possessed of reflecting power. I have had this important result verified by my assistant, M. Guénaire, and by several students in the Observatory.

"This process, so sensitive, evidently cannot serve for the tail, which occupies the whole field of vision, and does not moreover present very distinct limits. I have vainly tried other polariscopes—Savart's, for example. It would be very difficult besides to separate here the real polarisation of the tail from that of the atmosphere.

"In proportion as the light of the comet is diminished, the spectrum of the nucleus becomes paler; its colours, well pronounced on the earlier days, are no longer seen except on the side of the red; the bright bands retain their brightness. The green band is always distinctly limited in the less refrangible part. It will be interesting to know whether the comet, reduced to telescopic brightness, will at the same time have its light reduced to that of an atmosphere purely gaseous.

"On June 29, at 5h. 49m. sidereal time, during my polariscopic observations, a small star was found in the nebulosity, at a very short distance from the nucleus. Its image had not undergone any change, either of brightness or of form."

At the same *séance* M. Thollon communicated a note of spectroscopic observations of the comet as follows:—

"These observations were made with a direct-vision spectroscope which MM. Henry of the Observatory were good enough to lend me. The dispersion is that of an ordinary prism. A micrometer eye-piece, with point, giving 1-200th of a millimetre, enables one to make measurements of very high precision.

"In the night of June 24 I made my first observations and measurements. The nucleus presented then a very brilliant continuous spectrum, on which no trace of bands could be distinguished. On the violet side it extended beyond the line G. The parts next the nucleus likewise gave a continuous spectrum, on which the bands were still invisible; they only appeared a little further on and faintly. In the continuous spectrum I have thought I perceived several times a very complicated system of dark lines, and occasionally I believed I saw in the spectrum

bright parts having the aspect of short lines, not occupying the whole width of the spectrum. This was perhaps merely a result of fatigue of the eyes ; these phenomena were only produced during the first two nights.

"It appeared to me important to follow the modifications the spectrum might undergo as the comet went away from the sun. These modifications were produced with perfect distinctness. In the spectrum of the nucleus the violet radiations were extinguished first. About June 30 the most refrangible part, commencing with the green band ($\lambda = 516$), had sensibly lost its brightness and became invisible in the region G, while the yellow and red appeared to me as bright as on the first day. The bands, masked at first by the brightness of the continuous spectrum, became each day more visible in the neighbourhood of the nucleus, and during the night of July 1 they were perfectly distinguished on the nucleus itself.

"The measurements successively made of the bands of the comet and of those of the alcohol flame led me to conclude the identity of the two spectra. The green band however, the most brilliant, seemed a little more refracted in the comet than in the flame. To submit this matter to a decisive test, a total reflection-prism was adjusted on the slit so as to cover half of it. On placing the two spectra together I observed that they were strikingly similar when they had the same brightness, but that the green band appeared indeed more refracted in the comet when the spectrum of the flame was more brilliant. The comparison made directly between the two spectra, and the perfect coincidence of the bands, dispense with the necessity of giving numbers furnished by my micrometric measurements. They would not add anything to the certainty of the result.

"As to the violet band, it has not been possible for me to see it in a certain manner, even using a very small dispersion and a very small ocular enlargement. There is not in this fact anything surprising, if we take account of atmospheric absorption and of variations of brightness undergone by the violet band, when the experimental conditions are varied. We know that in the ordinary flame of alcohol it is very brilliant ; but if this flame be cooled by means of several folds of metallic sheeting, it becomes very weak and tends to disappear, while the other bands sensibly retain their habitual aspect.

"Continuing my observations till the present, I have found the continuous spectrum of the nucleus diminish progressively in brightness and extent, especially on the violet side. At present it has the aspect of a thin luminous thread, hardly passing beyond the line F. The bands, on the other hand, seem to have retained their intensity in the head of the comet. In the tail, and to a distance from the nucleus equal to twice or thrice the diameter of the head, they are still seen, but very faintly. Further on one sees only a continuous spectrum due perhaps to the light of the moon diffused by the haze, pretty thick during the last nights of observation.

"It seems to result from this that the cometary mass is formed in part of an incandescent gas, characterised by the spectrum of bands, and in part of solid or liquid matter, likewise incandescent, but in a state of extreme division, emitting a white light which belongs to it, and capable of reflecting in a certain proportion the light it receives from the sun. All the spectroscopic observations hitherto made on comets indicate the existence of carbon in the gases producing the band-spectrum. Dr. Huggins has given this conclusion a striking demonstration by showing, with photography, the existence of two bands of carbon in the ultra-violet spectrum of the comet.

"I have the honour to submit to the Academy three drawings representing (1) the spectrum of the alcohol flame, (2) the spectrum of the comet during the night of June 24, and (3) the same spectrum on July 1."

WIDTH OF MR. RUTHERFURD'S RULINGS

BY the direction of C. P. Patterson, the Superintendent of the U.S. Coast and Geodetic Survey, I have long been engaged in the precise measurement of a wave-length of light, in order to obtain a check upon the secular molecular changes of metallic bars used as standards of length. In advance of the publication of this work it may be useful to say I have found that the closest-ruled diffraction-plates by Mr. Lewis Rutherfurd have a mean width of ruling which varies in different specimens from 68078 to 68082 lines to the decimetre, at 70° F. There is a solar spectral line, well suited for precise observation, whose minimum deviation with one of Mr. Rutherfurd's plates in the spectrum of the second order with the closest ruled plates is 45° 01′ 56″ at 70° F. I would propose that this line be adopted as a standard of reference by such observers of wave-lengths as desire to escape the arduous operation of measuring the mean width of their rulings ; for by means of the measures which are shortly to be published it will be possible to deduce from the minimum deviation of this line produced by any given gitter, the mean width of that gitter, and consequently the wave-length of any other line whose deviation has been observed with it. The accuracy of this method will greatly exceed that of assuming Ångström's measures to be correct. The wave-length of the line in question (still subject to some corrections which may be considerable) is 5624825. Ångström gives 562336. C. S. PEIRCE

CITY AND GUILDS OF LONDON INSTITUTE

IT would seem as if at last, after long years of waiting, there were some hope that the views which for the last quarter of a century have been so persistently advocated touching technical education, were about to bring forth more fruit in London.

In season and out of season, since the note was first sounded by the late Prince Consort, one far-seeing advocate after another, and among these we must specially name Mr. Samuelson, Mr. Mundella, and Sir Henry Cole, have cried in the wilderness touching the need of more scientific instruction. At last it does seem as if there is an awakening, as if a part of the idea was realised in the Institute, the foundation-stone of which was laid at South Kensington on Monday by the Prince of Wales. No doubt in the building which has been begun a national school of science, theoretical and applied, worthy of a country like ours, may grow up. Mr. Mundella will rejoice that at last he has an opportunity of carrying out with something like adequacy the views on education of which he has been so long a strenuous advocate. We hope next week to give a detailed description and illustration of the new building ; and meanwhile will content ourselves with briefly referring to what took place on Monday.

The company present to receive the Prince of Wales was large and distinguished, including many eminent men of science. The Lord Chancellor, as Chairman of the Institute, addressed the Prince, expressing the gratification of the Council that His Royal Highness had consented to become president. The Lord Chancellor then traced the growth of the Institute and the efforts of the City Guilds to improve the technical education of the country.

"Since July of last year," the Lord Chancellor said, "the date of the incorporation of the Institute, its work has satisfactorily increased, and the Council have a lively and grateful recollection of the assistance and encouragement afforded to them by His Royal Highness, Prince Leopold, Duke of Albany, who in May last laid the foundation-stone of the Finsbury Technical College, a college that has been established by this Institute, and

which, when erected, will be the first building in the metropolis exclusively devoted to technical teaching. Pending the completion of the Finsbury College, instruction is being given to a large and increasing number of artisan students in some of the applications of chemical science to manufactures and industrial operations, and also in that new and widely opening field of labour and invention—the application of electrical science to the transmission and conservation of energy. Instruction will also be provided in that college, when finished, for those who are engaged in various handicraft trades, and it is hoped that this kind of teaching, which is gradually taking the place of apprenticeship in France, Germany, and Sweden, will help in this country to supplement, without supplanting, workshop training. The Institute is also endeavouring to advance technical education in a large number of towns in the United Kingdom by holding annual examinations in technology, and by encouraging, in connection with these examinations, the formation of evening classes for artisans, by assisting in the payment of teachers of technical subjects. During the early part of the present year more than eighty such classes were in operation, and it is satisfactory to know that the number of candidates recently examined by the Institute in different branches of technology was 1563 as compared with 816 in the previous year. But it is to the Central Institution," the Lord Chancellor went on to say, "the first supporting pillar of which your Royal Highness has graciously consented to set this day, that the Council look to crown their endeavours and give unanimity to all their efforts. In this college, from which the entire work of the Institute will be directed, instruction of a higher and more advanced character will be given, adapted to the wants of those who will be engaged in professional or commercial pursuits, in which a knowledge of some branch of mechanics, physics, or chemistry in its practical application will be found not only serviceable but almost indispensable. The building when completed will be supplied with laboratories, in which the most delicate operations can be carried on, with workshops in which the various branches of mechanical and electrical engineering will be taught, with studios in which applied art may be practised, and with a lecture-hall, theatres, and class-rooms in which the principles of science will be explained. Here, it is anticipated, will receive their professional training the sons of manufacturers, many of whom have hitherto been compelled to pursue their studies abroad—in Germany, in Switzerland, in France, or in America, in all which countries, for some time past, technical colleges, such as this Central Institution is intended to be, have already flourished. Here it is expected that artisans who have shown merit and have won distinction at the branch or provincial colleges will complete the training which may qualify them to act as managers and superintendents of works. Some of these, it is hoped, will obtain their education in this college by means of scholarships to be established by the Institute itself, possibly by provincial colleges, trade societies, or other public bodies, or by private individuals who may be interested in the promotion of technical education. And here it is anticipated will be trained that body of technical teachers, of whom there is in England at the present moment so great a need, who will carry with them from this college into the manufacturing centres, to be there imparted to other students, a knowledge of the theory and the practice of various crafts and industries. This institution will not be established as a rival to any other existing seat of learning; least of all to the excellent schools situated in this neighbourhood, which for some years past have been the means of offering to hundreds of young men and women a knowledge of the principles of science and art. The aim of this institution will be to supplement the teaching of those schools by giving instruction in the practical application of science and art to the trades and industries of the country, and by cultivating and endeavouring to stimulate inventive genius. It is therefore hoped and anticipated that the sister institutions, representing pure and applied science, will work in harmony with each other, forming an alliance, the effect of which will be to raise the intellectual *status* and to improve the technical knowledge and practical skill of the working classes of this country, and so to increase its industrial prosperity. It gives me great pleasure to be enabled to add that it has seemed fit to Her Majesty to recognise on this occasion the eminent services of Mr. Bramwell, the indefatigable chairman of the executive committee of the institution, by signifying Her Majesty's gracious intention of conferring upon that gentleman the honour of knighthood. It is anticipated that the cost of this building, when fully equipped with the apparatus and appliances needful for technical instruction, will not fall far short of 75,000*l*. Of this sum 31,000*l*. has been already subscribed by the worshipful companies of Fishmongers, Goldsmiths, Clothworkers, and Cordwainers; the grant of the Drapers' Company having been appropriated to the Finsbury College; and it is expected that about 24,000*l*. will be saved from the annual income of the Institute during the building of this college. The Council therefore, after paying the amount which is due, will have at their disposal only an estimated sum of about 55,000*l*., and they look to the liberality of the Livery Companies, both of those who have and of those who have not as yet subscribed to the funds of the Institute, to make good the balance of 20,000*l*., so that the building of this college may be completed at once and as a whole, in strict accordance with the plans."

The Prince of Wales in reply made some forcible and sensible remarks on the necessity to this country of improved technical education—education in things as contrasted with words—if we are to keep our place among the other industrial nations. "Other nations," the Prince said, "which did not possess in such abundance as Great Britain coal, the source of power, and iron, the essence of strength, compensated for the want of raw material by the technical education of their industrial classes, and this country has therefore seen manufactures springing up everywhere guided by the trained intelligence thus created. Both in Europe and in America technical colleges for teaching, not the practice, but the principles of science and art involved in particular industries, had been organised in all the leading centres of industry. England is now thoroughly aware of the necessity for supplementing her educational institutions by colleges of a like nature." The new building, the Prince remarked, will be of considerable benefit to the whole kingdom, not only as an example of the Institute devoting itself to technical training, but as a focus likewise for uniting the different technical schools in the metropolis already in existence, and as a central establishment also to which promising students from the provinces may, by the aid of scholarships, be brought to benefit by the superior instruction which London can command. The Prince reminded his audience that the realisation of the idea of such a college was one of the most cherished objects which his father had in view. "It is to me," the Prince stated, "a peculiar pleasure that the Commissioners of the Exhibition, of which I am the president, have been able to contribute to your present important undertaking, by giving to you the ground upon which the present college is to be erected with a sufficient reserve of land to insure its future development. By consenting at your request to become the president of this institute I hope it may be in my power to benefit the good work, and that our joint exertions, aided, I trust, by the continued liberality of the City and Guilds of London, may prove to be an example to the rest of the country to train the intelligence of industrial communities, so that, with the increasing competition of the world, England may

retain her proud pre-eminence as a manufacturing nation." Among the articles deposited in the stone were copies of the *Times*, *Nature*, and the *City Press*.

NOTES

THE Graham medal, instituted in connection with the Philosophical Society of Glasgow (Chemical Section), for the encouragement of chemical research, and open to competition to all chemists, has, on the recommendation of Prof. Williamson, F.R.S., the adjudicator in the competition, been awarded to Mr. James Mactear, F.C.S., F.I.C., for a paper entitled "Some Researches on the Reactions involved in the Leblanc Process of Alkali Manufacture."

THE fifty-fourth meeting of the German Association of Naturalists and Physicians will be held at Salzburg on September 18 24 next. From the list of addresses we note the following:—Dr. von Pettenkofer (Munich), on the soil and its connection with the health of man; Herr Meynert (Vienna), on the laws which govern human thoughts and actions; Dr. von Oppolzer (Vienna), on the question: Is Newton's law of gravitation sufficient for the explanation of the motion of heavenly bodies, and are there reasons to designate it only as approximately true? Herr Mach (Prague), on natural history teaching. All these addresses (besides one by Herr Weismann (Freiburg-im-Bresgau), the subject of which is not yet fixed) will be delivered at the general meetings. For the entertainment of visitors sufficient preparations will be made; the programme enumerates social gatherings, concerts, and excursions into the charming neighbourhood of Salzburg.

THE German Society for Anthropology, Ethnology, and Prehistoric Research will meet this year at Ratisbon on August 8-10 next. The programme of the meeting is a very varied one. In the first place the members will visit the curiosities and collections of the ancient city itself and the numerous Roman antiquities in the neighbourhood. At the Roman necropolis near Kumpfmühl some excavations will be made. Addresses will be delivered on the Roman period in Germany, on the period of serial tombs, on the pre-Roman metal age, on the stone period, and on anthropological questions generally.

ON Saturday the Prince of Wales opened, at South Kensington, the International Medical and Sanitary Exhibition which is being held in connection with the forthcoming Medical Congress. Up to the present nearly 2000 members of the medical profession have signified their intention of attending the Congress.

AT the Annual General Meeting of the Society of Arts medals were awarded as follows for papers read at the meetings of the Society:—Prof. A. Graham Bell, E. P. Edwards (of the Trinity House), Mr. Alex. Siemens, Sir Bartle Frere, Mr. J. Y. Buchanan, Prof. Perry, Sir Richard Temple, and Mr. J. M. Maclean.

AMONG recent valuable additions of models of ships to the collection now being exhibited in the galleries south of the Royal Horticultural Gardens is a whole model of the *Livadia*, showing in miniature all the details of that noted yacht. It is lent by the builders, Messrs. John Elder and Co. The London and Glasgow Shipbuilding and Engineering Company have lent half-block models of three of their steamships, and by an ingenious use of mirrors in mounting these the whole of each vessel is represented, and fore and aft views can be conveniently studied. There are many other admirable models.

THE geological distribution of endemic goître in England has been made the subject of a recent paper by Prof. Lebour of Newcastle. He shows that there is on the whole a striking sameness in the distribution in this country and in France, where Dr. de St. Lager of Lyons has fully investigated the facts. One important point only he considers to be established as common to those rocks on which goître does not occur—the absence of limestone together with that of metallic impurities. In both countries the rocks which support most goître are such as are both calcareous and metalliferous. But there are plenty of facts to show that metalliferous impurities alone cannot be credited with the origin of the disease, else the Devonian and the granite would surely not be free from it. Neither will the absence of limestone alone be sufficient to check the growth of the disease, else the lignitiferous beds of France and the ferruginous sands of the Weald would not support it. (Dr. de St. Lager's conclusion is that endemic goître coincides with metalliferous deposits, iron pyrites being in the first rank.)

THE Handbook of the Vertebrate Fauna of the County of York, by W. E. Clarke and W. D. Roebuck, the secretaries of the Yorkshire Naturalists' Union, is expected to appear about the beginning of August. The work will show what species are, or have been, within historical periods, found in Yorkshire. The authors are enabled to enumerate, as such, 508 species out of a total British list of 756, a fauna superior in numerical extent to that of any other county in the British Isles. The list includes 46 mammals, more than 300 birds (doubtful species being excluded), 12 reptiles and amphibians, and upwards of 150 fishes. For comparison, the British species *not* found in Yorkshire are also enumerated. Application should be made to the above-named gentlemen, 9, Commercial Buildings, Park Row, Leeds.

THE Marine excursion of the Birmingham Natural History and Microscopical Society to Oban this year, which extended from July 1 to July 12, proved a great success, and fully answered the expectations of its promoters. Thirty-two Members joined the excursion, including Dr. Thomas Wright, F.R.S., the President of the Midland Union of Natural History Societies, and Mr. E. D. Hamel, Ex-President of the Tamworth Natural History Society. There were also several ladies. A little steamer—the *Curlew*—of about twenty-five tons burthen, was chartered for a week. Dredging operations were carried on daily in the Bay of Oban and the neighbourhood in depths varying from fifteen to fifty fathoms, under the superintendence of Mr. Edmund Tonks, B.C.S., and Mr. W. R. Hughes, F.L.S. A most interesting and beautiful collection of animals was taken. The specimens included fine examples of the Alcyonarian zoophytes. The Echinoderms embraced many genera from *Antedon* (*Comatula*) through the group to *Holothuria*. The Mollusca were not very numerous, but they included several rare forms. A few interesting fishes were taken, including the Lump-Sucker. The specimens will be examined by specialists and reported to the Society in due course. Those Members who did not engage in the dredgings had good opportunities of botanising and geologising, the indefatigable honorary secretary, Mr. Morley, having arranged a series of excursions to the principal places of interest in the district. On Sunday evenings July 3 and July 10, Dr. Wright also gave by request addresses "On the Basaltic Formations of Staffa and Iona," and "On Glaciation," which afforded great gratification to the Members. In the evenings demonstrations were given by the microscope and otherwise on the more interesting forms of life taken, by Prof. Bridge, Mr. W. P. Marshall, Mr. W. R. Hughes, and Mr. G. W. Tait. By the courtesy of Mr. R. H. Scott, of the Meteorological Office, telegrams were received daily, giving the weather forecasts for the morrow, which enabled the members to make their arrangements. At the termination of the excursion votes of thanks were accorded to the leaders of the party, who rendered assistance in various ways, and a resolution was passed selecting the Channel Islands as the place for the next marine excursion.

THE German Government has been requested by many eminent hydrologists to establish a hydrological "Reichs-Centralstelle." They consider hydrological researches extending over the whole Empire necessary for the general welfare with regard to the utilisation of water and for the general protection of arable lands against floods and inundations. As these researches would necessarily often be combined with meteorological observations, it is proposed to connect the Hydrological Office with the Meteorological Central Office. The work would have to be done principally by hydrologists and meteorologists, but the staff would have to comprise geologists, agriculturists, and forest-rangers.

THE news that in the Pastorat Moor of Dejbjerg (district of Rinkjöbing, Jütland) a carriage of the fourth or fifth century has been discovered, causes great sensation in archæological circles. At the beginning of this year the Museum of Northern Antiquities of Copenhagen received several bronzes which had been found in the moor in question, which unquestionably had originally been carriage ornaments. Perfectly similar bronzes had been found a few years ago at Broholm (Fünen) in a tomb, and had been explained as ornaments of a wooden carriage which had been burned with the dead. The discovery in the Dejbjerg Moor now confirms this view. Dr. H. Petersen, who also conducts the excavations at Broholm, was intrusted with the investigation of the Dejbjerg Moor, and his researches show that the fragments now found belonged to a state carriage with neatly turned spars and fine bronze ornaments on the wheels and sides. Apart from the carriage fragments only a few clay vessels were found. They all date from the migration period.

THE Archæological Society at Athens has purchased the land at Eleusis necessary in order to excavate the temple of Ceres. News from the director of the excavations at Epidauros state that the theatre excavated in the forest of Asklepios is the second largest of Ancient Greece and a masterpiece of the architect Polykleitos. Even the headless statue found there, which is supposed to represent Hygieia, is believed to be a work of Polykleitos.

THE Museum of Antiquities at Sparta is reported to have been broken open and robbed of many objects.

AS we anticipated in our last issue, M. Berthelot has been nominated a life-member of the French Senate almost unanimously. It may be noted that it is just twenty years since M. Berthelot received the great prize of the Academy of Sciences for his method of producing artificially substances which have been found only in living bodies.

A SAD accident has happened in the vicinity of Lyons, where two balloons were sent up on the occasion of the *fête* of July 14. A match having been ignited close to the place where the largest landed, the balloon exploded instantaneously with a fearful crash. Three people were severely wounded.

M. DE MÉRITENS, the well-known electrician, tried a new system of electrical illumination on the occasion of the festivities of July 14. He suspended his regulators between two poles placed on each side of the Boulevard des Italiens and fifty feet high. A series of four of these regulators were placed at a distance of about 200 feet from each other. The effect was much approved by a large number of people.

A SPECIAL competition has been opened for erecting a statue to Carnot, the celebrated mathematician and politician of the First Republic. The number of competitors exceeds fifty, and some of the works sent are highly creditable to their authors. The statue is to be erected by public subscription at the birthplace of Carnot, Nolay, in Côte d'Or.

OUR Paris correspondent informs us that Philippart and Sons are preparing to work tramways at Roubaix with improved Faure batteries, and that experiments will also shortly be made in London. Our correspondent witnessed some preliminary experiments which he thinks give room for high expectations. One of the most important changes is the substitution of flat for round sheets, which produced numerous cracks in the minium coating, and had been resorted to in imitation of the old Planté batteries.

AT the anniversary meeting of the Sanitary Institute of Great Britain held at the Royal Institution, Albemarle Street, on Thursday, July 14, the Right Hon. Earl Fortescue in the chair, an address was delivered by Prof. F. S. B. F. de Chaumont, M.D., F.R.S., chairman of the Council, entitled "Modern Sanitary Science," and the medals and certificates were awarded to the successful exhibitors at the exhibition held at Exeter in October, 1880.

THE forty-seventh anniversary meeting of the Statistical Society was held in the Society's rooms, King's College, Strand, on the 28th ult., Dr. W. A. Guy, a past president, in the chair. The report was highly satisfactory, showing that in the last decade the number of Fellows, the income, and the amount invested have been more than doubled, while the expenditure had increased in a less ratio A new edition of the Library catalogue is being prepared. Ten papers had been read during the year. The president for 1881-82 is James Caird, C.B., F.R.S.

A SECOND earthquake is reported from Metkovich (Dalmatia). It was observed on June 14 at 5.27 a.m. During the night of May 17 a violent shock occurred in Haiti, causing several landslips, through which a large number of cattle perished. The volcano in the Gulf of Santorin, which has been inactive since 1870, again began to eject vapour on May 30 last. This activity increased considerably on June 2. The sea between Pala and Aeo Kaymene has again become heated. Earthquakes are reported from the east coast of Tunis. It is stated that since June 10 last Gabes and neighbourhood was visited by a great many violent shocks, some recurring at very short intervals. The last shock was felt during the night of June 22-23. The mountains in the neighbourhood of Gabes are of volcanic nature; smoke rises during the night from the Ay-Buin Mountain (about 30 kilometres to the north-west of Gabes), and at Hamma, 18 kilometres from Gabes, there are hot springs. Shocks of earthquake are reported from different places in Dalmatia: Ragusa on July 4, at 10.28 a.m.; Budua, Castelastua, Sutomore, on July 4, at 10.19 a.m. and 1.53 p.m.; duration, two to four seconds; direction, north to south.

THE growth of American journalism is shown by recent census results to have been much more rapid than that of English. In 1824 there were eleven daily newspapers in Philadelphia and twelve in New York, with a circulation varying from 1000 to 4000 copies. To-day the State of New York has 115 daily newspapers and 84 weeklies, with a combined annual circulation of 384,328,454; and Pennsylvania 98 daily newspapers and 57 weekly papers, with a combined circulation of 202,539,482. There are 962 daily newspapers in the United States, and 803 weekly, semi weekly, tri-weekly, and Sunday newspapers. The total circulation of all newspapers is estimated to be 1,344,101,235, the bulk of which is in ten great States.

FROM a recent U.S. Census Bulletin relating to the Fishery Industries of the Pacific States and Territories (California, Oregon, Washington, and Alaska) we gather that the total number of persons engaged in these fisheries is 16,745, of whom 7910 are Esquimaux, Aleuts, and Indians, and about 4000 Chinese. A capital of over 2½ million dollars is invested in vessels, boats, apparatus, building, &c. There are 53 vessels and 5547 boats. Among other items in this Bulletin we note that the number of salmon caught in 1880 (to which all these

numbers refer) was 2,755,000, with a total weight of 51,862,000 lbs. The number of sealskins obtained was 155,718, valued at 1,540,912 dollars.

M. FERRY has ordered the teachers of elementary classes of the colleges to conduct their pupils into the galleries of the Museum of Natural History at Paris, to explain to them the differences of the several kinds of animals, plants, and minerals, and to incite young pupils to collect specimens during their walks in the country round Paris.

AN attempt at silk cultivation is to be made at Akaron, New Zealand, the valleys and bays of Banks' Peninsula being considered well suited for that purpose. The Colonial Government are sending to California and Japan for silkworms' eggs and mulberry trees of the best kinds, with the view of encouraging the industry.

THE *Colonies and India* reprints from a New Zealand paper some notes on a discussion at the Otago Institute, when Prof. Parker exhibited the skin and body of the extremely rare and remarkable bird, *Notornis Mantelli*. The specimen in question is only the third which has ever been captured, was caught low down on the ranges, and it is probable that an expedition will be fitted out to search for more of the species.

A POPULAR explanation of Kant's "Kritik der reinen Vernunft," by Albrecht Krause, has just been published by Moritz Schauenburg of Lahr (Germany), "in celebration of the centenary of the publication of the great work."

AN important invention relating to railway signals has recently been made in Germany, and the model apparatus has just been completed at the central works of the Bergisch-Märkische Railway Company at Witten. The model will be exhibited at the Electro-Technical Exhibition at Paris.

THE additions to the Zoological Society's Gardens during the past week include a Red-handed Tamarin (*Midas rufimanus*) from Surinam, presented by Mr. Keiser; an American Black Bear (*Ursus americanus*) from Nova Scotia, presented by the Earl of Caledon, F.Z.S., and the Hon. Charles Alexander; two Grey Ichneumons (*Herpestes griseus*) from India, presented respectively by Mr. C. R. Smith and Mrs. C. Hassell; a Common Raven (*Corvus corax*), British, presented by Major Botts; a Carrion Crow (*Corvus corone*), European, presented by Miss Mortimer; a —— Monitor (*Monitor*, sp. inc.) from Ceylon, presented by Mr. E. Lindstedt; a Sykes' Monkey (*Cercopithecus albogularis*), three Vulturine Guinea Fowl (*Numida vulturina*) from East Africa, deposited; three Common Peafowl (*Pavo cristatus*), two Cheer Pheasants (*Phasianus wallichii*), two Horned Tragopans (*Ceriornis satyra*), a Siamese Pheasant (*Euplocamus prælatus*), bred in the Gardens.

METEOROLOGICAL NOTES

FROM a discussion by Dr. Hann of a series of hourly summer observations of air-pressure, temperature, moisture, cloudiness, and force of wind made by the U.S. Engineer Corps on the plateaux of the Rocky Mountains (the stations lying between 3500 and 8500 feet above the sea), it appears that in valleys and wide basins, even at the greatest height, the influence of the daily barometer oscillation in summer is still very great, and no decrease with the height is noticed. The course of the curve is of the continental type, a comparatively large afternoon minimum, a slightly marked morning minimum, and an earlier occurrence (7 to 8h.) of the morning maximum. In the temperature-curve the most notable point is that the maximum is very near midday, or little behind the culmination of the sun. The maximum of absolute moisture occurs about 8 a.m., and a second smaller maximum in the afternoon or evening. The maximum of cloudiness and wind-force occurs between 3 and 4 p.m., the minimum between 3 and 4 a.m.

IN a letter dated April 14, Mr. Russell of the Sydney Observatory remarks that the rain return for 1880 shows it to have been a dry year in New South Wales, as in many other parts of the world; but the want of rain was not severely felt because it came at favourable times for grass. Perhaps the most curious consequence of the short supply of rain was the stoppage of the river navigation for a considerable part of the year, thus preventing the wool from going by steamer to market, and increasing the cost of all stores consumed: the river curves show, for instance, that at Bourke the water was at summer level from June to October, thus preventing navigation. Mr. Russell hopes, by the combination of the rain and river observations, to find an answer to a local question of very great importance, viz. the *amount* and *source* of the water found in wells which are being sunk by the hundred in the inland parts of the colony. There can be no doubt that all, or nearly all, the water brought down in such abundance from Tropical Queensland by the Culgoa, Warego, and Paroo Rivers sinks into the ground before it reaches New South Wales, and there is good reason for thinking that much of the water brought down by the heads of the Darling sinks into the ground before it reaches Bourke. If this can be proved, which he thinks can be done in the course of a few years, there will be no fear for the abundance and permanence of the well-water. And when it is remembered that in most cases the water rises to within thirty or forty feet of the surface, in many instances to the surface, and in one case twenty-six feet above the surface, the local importance of the question will be obvious.

IN studying the conditions of temperature of the Russian Empire some time ago, M. Wild found that the irregular distribution of temperature revealed by the isotherms might be elucidated by means of "isanomals" (or lines of equal temperature-anomalies). Among the causes of the isanomals special regard must be had to the wind, which again immediately depends on the distribution of air-pressure, as shown by the isobars. A comparison of the lines of equal pressure with the lines of temperature-anomalies thus suggested, led M. Wild to recognise an intimate relation between the two systems. Reasoning from the results arrived at, he has attempted with some success to rectify the isobars over certain regions, where from want of observations their course was somewhat uncertain; and further has even suggested the probable existence of a pressure-maximum in Northern Siberia, of which region however little if anything is positively known, owing to the want of barometric observations. M. Wild's paper, which is of a provisional nature, appears in the *Bulletin* of the St. Petersburg Academy. (It is noted that M. Teisserene de Bort, in the Paris Academy, has to a certain extent been prosecuting the same subject.)

AS an evidence of the great cold of last winter Mr. Angus M'Intosh, Schoolhouse, Laggan, states in the *Scotsman*, that on June 20 the Balgown peat moss in that parish was still frozen at the depth of 2½ feet beneath the surface.

THE *aurora* has been remarkably frequent at Stykkisholm, Iceland, last winter. From September 5, when the first aurora of the season was observed, to February 28, to which date the observations have been received, auroras were seen on forty-five nights, viz., five in September, eleven in October, four in November, eight in December, twelve in January, and five in February, the phenomena being very brilliant on September 29, December 23, January 31, and February 5.

FOR some time the Registrar-General has been printing in his weekly returns the deaths from small-pox in London under three heads, viz., the vaccinated, the unvaccinated, and those regarding whom no statement is returned. The results show for the whole mortality from small-pox substantially the small-pox curve as given in NATURE (vol. xxiv. p. 144), with its characteristic saddle-shaped maximum, the dip between the two heights of the curve being towards the end of March. On projecting curves of the death-rates for the vaccinated and the unvaccinated, it is seen that the dip in the curve for the whole mortality is due to a diminution of the deaths of the unvaccinated during March as compared with what occurred before and after. In other words, those climatic influences which raise the mortality from small-pox to the annual maxima, first in January-February, when the weather is coldest, and again in May when driest, bear with more fatal effect on the unvaccinated than the vaccinated. As fatal terminations in small-pox cases arise chiefly from complications with other diseases, and as the times of maxima of the curve point to diseases of the nervous system and the respiratory organs as those mostly concerned, even one year's results, particularly a year with cold and dryness so unusually pronounced, may be pointed to as warranting an inquiry of some importance into the relations of the vaccinated and unvaccinated to attacks of small-pox.

SOLAR PHYSICS—THE CHEMISTRY OF THE SUN[1]

I.

WHEN we have familiarised ourselves with the general phenomena presented to our notice by the analysis of the light proceeding from different sources, and wish to apply this knowledge to the study of the sun, the first work to which attention must be given is a very admirable memoir of Kirchhoff (1861).[2]

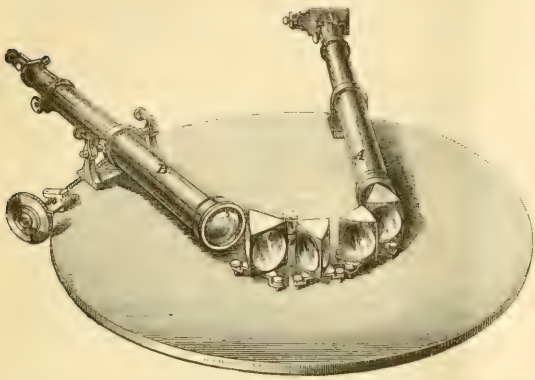

FIG. 1.—Steinheil's form of four-prism spectroscope. A, collimator; B, observing telescope.

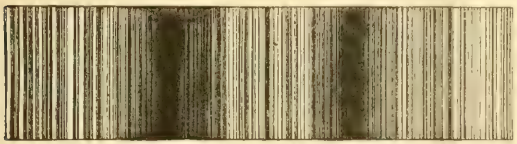

FIG. 2.—Copy of a photograph of the solar spectrum in the region of the thick calcium lines, by Lockyer.

In this, after referring to the prior work of Fraunhofer and others, he goes on to show that the same principles which had then been employed to suggest the extreme probability of the existence of sodium in the atmosphere of the sun, and the probability, therefore, that the dark line D, which we see in the spectrum, was caused by the absorption, by the cooler sodium vapour, of light proceeding from the solar nucleus which was hotter than the vapour; might be applied to other substances, such as iron, cobalt, nickel, and so on; and that if these were experimented on in the same manner, other of the dark lines in the solar spectrum might be explained.

Now I propose, in the first instance, to show what Kirchhoff saw, and what he did—his manner of work. Kirchhoff, and after him Ångström and Thalèn, to whom further reference will be made presently, used spectroscopes placed close or nearly close to the source of light. Kirchhoff's work was done by a spectroscope of this model. We have a slit and collimating lens, a train of prisms, which, of course, during the observations are carefully covered up, and the observing telescope. This instrument may be turned to the sun, or to a cloud illuminated by the sun in case the quantity of light which enters the instrument when turned directly towards the sun is too great to allow of easy observation; or light from the sun or a cloud may be reflected into the instrument by a mirror. Kirchhoff was enabled by means of properly contrived measuring apparatus to map down the positions of the lines observed.

Let us see, first of all, what kind of thing Kirchhoff saw. To give an idea of this I propose to throw on the screen photographs of that portion of the spectrum which is not so readily observable as that upon which Kirchhoff began his work. Here then is an absolutely untouched photograph of a part of the solar spectrum in the blue and violet (Fig. 2). We get in great prominence in the spectrum two very thick lines, which are called H and K, the precise position of which in the solar spectrum are shown by means of the diagram of the spectrum (Fig. 3). By moving his observing telescope along the spectrum, as it were, the telescope being furnished with a delicate micrometer, or some properly-contrived means for defining the exact position of each line, Kirchhoff was in that way able to prepare a map of the whole spectrum. Indeed he did prepare this map with the object of providing himself with a scale of extreme value for the future work which he then laid out for himself. The future work being this:—he wished to determine the positions of the bright lines given by the different chemical elements; having got this information, he

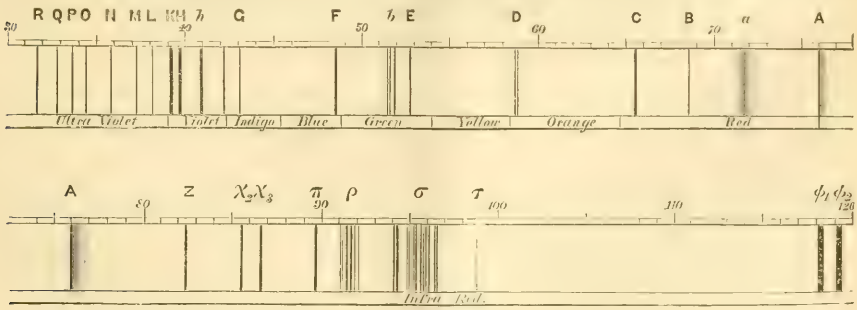

FIG. 3.—Wave-length map of the solar spectrum, including the infra-red.

wished to put the same question to the solar spectrum with regard to each of those elements as already had been done in the case of sodium. How then did he propose to do this? He made an addition to the slit of the spectroscope, such as was then employed. He put a prism in front of it, by means of which he illuminated one half of the slit with the direct light of the sun, and the other half with the light from the vapour employed

[1] Lectures in the Course on Solar Physics at South Kensington (see p. 150). Revised from shorthand notes. The first lecture is omitted, as it dealt with the general principles of spectrum analysis.

[2] "Researches on the Solar Spectrum and the Spectra of the Chemical Elements." *Transactions* of the Berlin Academy for 1861. Translation by Prof. Roscoe (Macmillan, 1862).

reflected on to that other half by means of the prism. You will see in a moment, therefore, that it was quite easy by this

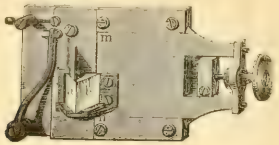

FIG. 4.—Steinheil's slit, showing reflecting prism.

method to see in his observing telescope no longer the spectrum of the sun alone, but the spectrum of the sun together with the

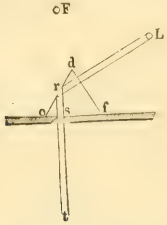

FIG. 5.—Path of light through comparison prism. *d f o*, prism, *l*, light source; *r*, point of reflection; *s*, slit; F, light source in front of slit.

spectrum produced by each of the chemical substances which he chooses to experiment upon.

Again, anticipating matters somewhat, I can show you something like what Kirchhoff then saw—only again I give you a photograph, and therefore we have a part of the spectrum with which he did not begin his work. In the lower half of this slide we have the solar spectrum. There are the two lines H and K, and in the upper portions we have the bright lines given us by a metallic element—in this case cerium. You see when some of the metallic elements are treated in this way they have a trick of giving us very complicated spectra.

(The photograph was projected on the screen.)

I will show you the iron spectrum which Kirchhoff worked upon. The point was to determine which of the bright lines corresponded with the dark Fraunhofer lines. Over the whole visible reach of the spectrum Kirchhoff mapped the results, for iron; I will give one or two extracts from his paper. He says,[1] "It is specially remarkable that coincident with the positions of the bright lines which I have observed [that is the bright lines from the vapour of iron, using two iron poles with an induction coil] definite dark lines occur in the solar spectrum. By the help of a very delicate method of observation which I have employed, I believe that each coincidence observed by me between the iron lines and the lines of the solar spectrum, may be considered to be at least as well established as the coincidence of the sodium lines." Then he shows, limiting his attention to sixty of the most defined iron lines in the region included in his map, that the betting that there was iron in the sun was about three trillions to one, dealing alone with the absolute matching of the positions of the lines recorded in the solar spectrum. Then he goes on to show that this probability of three trillions to one was rendered still greater by the fact that the brighter a given iron line is seen to be the darker as a rule—and I beg you to mark those words "*as a rule*"—does the corresponding solar line appear. Hence this coincidence must be produced by some cause, and a cause can be assigned which affords a very perfect explanation of the phenomenon. He then gives the cause, which has already been stated by Prof. Stokes.

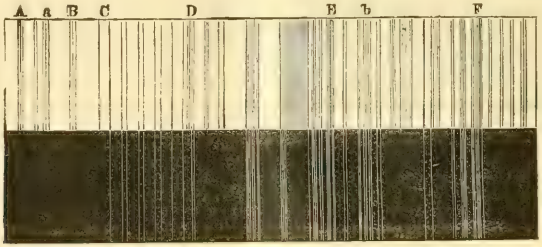

FIG. 6.—Coincidence of some of the bright lines of iron with some of the Fraunhofer lines.

Now before I go further I must point out that there is a considerable assumption here. It is quite easy in an electric lamp to produce the vapour of a meteorite or of any of our terrestrial rocks, to throw their spectra on the screen, and to map them with considerable minuteness; and we say we have the spectrum of such and such a meteorite, or of such and such a rock. Similarly we can get the spectrum of iron terminals, and serve that in the same way, and we are considerably astonished at the wonderful similarity of the results thus obtained. Now chemistry has advanced to a certain stage, and low temperature chemistry comes in and shows us that this meteorite or rock may be an excessively complicated substance. The same chemistry applied to iron shows that nothing can be done with it. But to say that iron cannot be broken up because low temperature chemistry fails to break it up is, you will see, an assumption, for as we undoubtedly get the lines of the constituents of the rock, or of the meteorite, recorded in the spectrum, we may also be registering the lines of the constituents of iron; and it is fair to say this, because we know that in the electric arc we have a stage of heat at which at present no experiment whatever has been made.

Passing on from that point, however, I will ask you to consider somewhat more in detail that part of Kirchhoff's work which deals with the connection between the solar spectrum and the spectra of the chemical elements.[2]

Confining his observations to the region of the solar spectrum between F and D, Kirchhoff found the following coincidences between lines in the spectra of certain elements and the Fraunhofer lines:—

	Lines.		Lines.
Sodium	2	Iron	42
Calcium	13	Chromium	4
Barium	7	Nickel	28
Strontium	2	Cobalt	10
Magnesium ...	3	Zinc	2
Copper	3	Gold	1

Hofmann[3] continued these researches on both sides of the region observed by Kirchhoff as far as A on one side and G on the other, and in addition investigated the spectra of the following metals:—Potassium, rubidium, lithium, cerium, lanthanum, didymium, platinum, palladium, and an alloy of iridium and ruthenium. Hofmann added the following coincidences between

[1] "Researches on the Solar Spectrum." Roscoe's translation, Part I., p 18.

[2] Kirchhoff's "Researches," translated by Roscoe, Part I., Supplement.

[3] *Ib.*, Part II., Appendix.

lines of the spectra of the different chemical elements and the dark solar lines :—

	Lines.		Lines.
Calcium	16	Chromium	0
Barium	5	Nickel	4
Strontium	2	Cobalt	4
Magnesium ...	0	Zinc	3
Copper	1	Cadmium	2
Iron	31	Gold	1

The spectra of the additional metals examined gave the following coincidences :—

	Lines.		Lines.
Cerium	2	Platinum	1
Didymium	2	Rubidium and Iridium	1
Lanthanum ...	1		
Palladium	2		

The potassium spectrum could not be obtained by moistening the electrodes with salts of this metal, and when poles of the metal were employed the spectrum was so very feeble that only two prisms could be employed, and hence the position of the lines with regard to the solar lines was not easily determined. He noted that the line Kα was better seen if the Bunsen flame was used instead of the electric spark.

In conclusion Kirchhoff and Hofmann state that, although the additional observations have added nothing to what the previous work had taught, they have confirmed the results of the previous examination. A large number of lines of iron and of calcium occur in the yellow and the blue, and all these were found coincident with well-defined Fraunhofer lines. The probability that nickel is present in the solar atmosphere is greatly increased by the number of new coincidences observed. Cobalt remains doubtful, the solar lines coincident with a considerable number of its bright lines not having been observed. New coincidences in the spectra of barium, copper, and zinc with dark solar lines confirm the presence of those elements in the sun's atmosphere. In the cases of strontium and cadmium the number of coincidences seemed to be too small to warrant the conclusion that those metals are in the sun. The other chemical elements examined, including potassium, did not appear to be visible in the solar atmosphere. The case of potassium however they consider as doubtful, since faint solar lines are very near the red potassium lines.

Note that the passage from the spectrum of the spark to the spectrum of the sun lands us in doubt in many instances.

Kirchhoff next discusses the bearing of this work on the physical and the chemical condition of the atmosphere of the sun. Of course this at once destroyed, at a blow, the idea of Sir William Herschel that the sun was a cool habitable globe with trees, and flowers, and vales, and everything such as we know of here. If the atmosphere were in a state of sufficient incandescence to give these phenomena it was absolutely impossible that anything below that atmosphere should not be at the same time at a higher temperature. He says, "Judging of the height of the solar atmosphere from the phenomena observed in a total eclipse of the sun, it cannot be small in comparison with the radius of the body, and hence the distances which two rays have to pass, one of which proceeds from the centre, and the other from the edge of the disk, do not greatly differ." That was a reply to an objection which had been urged to the effect that if a dark line had been produced by anything absorbing in the atmosphere of the sun, there would be a very considerable difference between the spectrum of the sun's limb and the spectrum of the sun's centre, for the same reason, *ceteris paribus*, that the sun is white at noon-day and reddish at sunset; for since our atmosphere is thin, the light passes through a greater stratum in the one case than in the other. At the sun the light would have to do the same thing, and we should get, therefore, a greater darkening of the limb than is actually observed. He says :—"In addition to this we must remember that the lowest layers of our terrestrial atmosphere are those in which the distance traversed by the light increases most rapidly when approaching most nearly the horizon; for the solar atmosphere, on the contrary, it is those layers which are elevated to a certain position above the solid crust of the sun which are more energetic in producing dark lines than the lower layers which possess a temperature slightly different, and effect but little alteration on the light." He therefore places the region where this absorption takes place at a considerable elevation in the atmosphere of the sun. His notion is that the sun we see is what gives us the continuous spectrum the light of which is absorbed; that above that there is a haze different in structure from it, and yet not competent to give us the absorption lines; that practically none of the absorption phenomena arise from that stratum, but that above this very luminous region of haze the absorption phenomena take place. Such was Kirchhoff's view.

We now pass on for some years to the next step, the work of another eminent man no longer amongst us, Ångström.[1] He took up very nearly the same work as Kirchhoff did, and extended it in certain directions; but he did the work in a different way instrumentally. He was not content with the kind of scale which Kirchhoff had employed, a scale dependent on the construction of his instrument. He wished to have a natural scale. He therefore rejected the use of prisms, and used a diffraction grating. By means of this he obtained what was called, and what is still called, a normal spectrum; and having obtained this he, as Kirchhoff had done before him, endeavoured to determine the coincidence, or want of coincidence, of metallic lines.

By the use of these diffraction gratings measured with great care and expressed in terms of the standard metre, along with a collimator and reading-telescope, the latter fitted with a micrometer screw which enabled the operator to determine with great accuracy the angle through which it moved, Ångström was able to determine with great exactness the wave-lengths of the more prominent line of the solar spectrum from A to H. Using these lines as starting-points he was able, by means of the micrometer, to measure the angle between any of these points and any line which lay between them, and then writing these determinations in interpolation formulæ he was able to compute the wave-length of any observed solar line.

The wave-lengths are given to the second decimal place, the unit being $\frac{1}{10000000}$th of a millimetre.

In the atlas which accompanies this memoir of Ångström the scale is divided, so that one division corresponds to $\frac{1}{10000000}$th of a millimetre of wave length. In addition to marking the wave-lengths of the solar lines, their relative intensities are shown. The map also shows the origin of each line and its correspondence with the lines of metallic spectra so far as these have been determined by Ångström and Thalén.

The following is a summary of the coincidences observed[2] :—

	Lines.		Lines.
Hydrogen	4	Manganese... ...	57
Sodium	9	Chromium	18
Barium	11	Cobalt	19
Calcium	75	Nickel	33
Magnesium ...	4 (3?)	Zinc	(2?)
Aluminium ...	2 (?)	Copper	17
Iron	450	Titanium	118

Ångström remarks that the number of these lines, about 800,[3] might easily be increased by raising the metals to a higher stage of incandescence. Still, he observes, the number already found is quite sufficient to enable him to refer the origin of almost all the stronger lines of the solar spectrum to known elements, thus confirming the opinion he had expressed in a previous memoir, that the substances which constitute the mass of the sun are doubtless the same as those forming that of the earth. But, he says, the fact must not be lost sight of that there exists, nearly midway between F and G, strong solar lines of which the origin is entirely unknown: still it would be premature to assert that the substances to which these are due are not constituents of our globe.

Of aluminium he says[4] that although it gives brilliant lines in different parts of the spectrum, yet the two lines situated between Fraunhofer's two H-lines are the only ones which appear to coincide with solar lines. By way of explanation of this phenomenon he points out that the violet rays are much the strongest in the spectrum of this metal. He observes that these two lines often present the same phenomenon of absorption as is shown by the yellow sodium lines, which is a proof of their great intensity. He states finally that the point will be cleared up by ascertaining whether the ultra-violet lines of aluminium coincide or not with faint solar lines in that region.

Of zinc he remarks[5] that the two lines he has given of that metal as coincident with solar lines do not correspond with the latter in character, being wide, very strong and nebulous, so that

1 "Recherches sur le Spectre Solaire" (Upsal, 1869).
2 *Ib.*, p. 35.
3 *Ib.*, p. 36.
4 *Ib.*
5 *Ib.*

the presence of zinc in the sun remains doubtful. It is noteworthy, however, that there are three lines in the magnesium spectrum which present the same nebulous appearance, and to which there are no corresponding solar lines, and yet magnesium is undoubtedly present in the sun.

Kirchhoff's and Angström's maps are in all our laboratories, and there is a very considerable difference between them. This difference arises from the fact that whereas Kirchhoff used an induction coil and spark, Ångström varied his experimental method by placing no longer a spark, but the electric arc in front of the slit of his instrument. In this case, therefore, he was determining the spectrum which was produced at the temperature of the electric arc instead of the spectrum which was produced at the temperature of the induction coil. The result of their combined attack is shown in the accompanying table :—

Elements present in the Sun

Kirchhoff.	Ångström and Thalén.
Sodium.	Sodium.
Iron.	Iron.
Calcium.	Calcium.
Magnesium.	Magnesium.
Nickel.	Nickel.
Barium.	—
Copper.	—
Zinc.	—
	Chromium.
	Cobalt.
	Hydrogen.
	Manganese.
	Titanium.

So far then for that mode of observing the sun which consists in comparing the total light of the light-source with the total light of the sun.

This introduces an important consideration. When we have a light source placed in front of the slit of the spectroscope it is perfectly clear that light from all portions of the light source must illuminate the slit. Similarly, if we content ourselves by pointing the spectroscope to the sun, or to a cloud illuminated by the sun, it is perfectly obvious that the light from all parts of the sun must enter all parts of the slit.

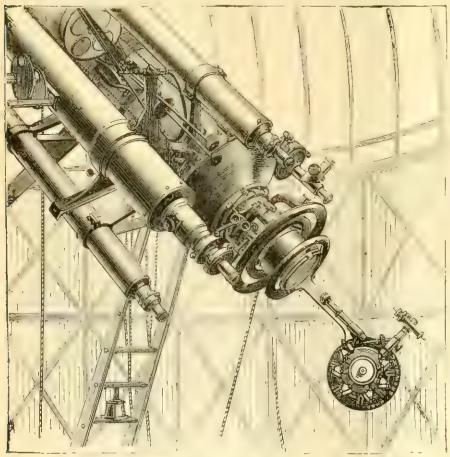

Fig. 7.—The eyepiece end of the Newall refractor (of 25 inches aperture) with spectroscope attached.

Is there any other way of observing the sun along with the light source? You will see in a moment that there is. *We can throw an image of the sun on the slit of the spectroscope.* This work was begun in 1866. If an image of the sun contains, let us say, a spot or a facula, we can see it when we throw it on to the slit. If we can manage to do so we shall get the spectrum of the sun-spot as distinguished from the spectrum of the other portions of the sun, or we shall get the spectrum of the facula as opposed to the spectrum of the other portions of the sun. The manner in which this kind of work is carried on is easily grasped. It simply consists in the use of a spectroscope of large dispersion attached at the focal point of a telescope of considerable power. Here is the eye-piece end of Mr. Newall's refractor, with a spectroscope, with a considerable number of prisms, fixed to the telescope by means of an iron bar, with the slit of it in the position of the focus, so that when the instrument is pointed towards the sun we see an image, in the case of this telescope something like four inches in diameter, with the spots and brighter portions wonderfully and beautifully clear, and by means of the different adjustments of the telescope we can bring now a spot, and now one of the brighter portions of the sun on to the slit, and see if there be any difference between the spectrum of the spot and the spectrum of the general surface of the sun.

If we wish to observe two adjacent spots and compare their spectra, we can rotate the spectroscope and look at both. Again, anticipating matters, I can show what we see to a certain extent, for latterly we have been fortunate enough to obtain some photographs of the spectra of sun-spots.

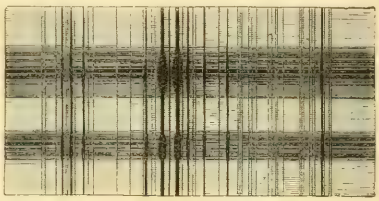

Fig. 8.—Spectrum of Sun-spot, showing the widening of the D lines.

The dark portion gives us the spectrum of the spot throughout the whole length of the spectrum. That is a case of continuous absorption. The continuous radiation of the sun is cut off, but independently of this continuous absorption some of the lines are considerably thickened in the nucleus of the spot (Fig. 8). Now the lines observed in the first instance were the lines of sodium, and the point of the observation was this. Two rival theories had been suggested to explain how it was that the sun-spot was dark. One school said it was due to absorption, and another that it was due to the defect of radiation from the interior gases of the sun. If we had been dealing with defective radiation, we should still have been dealing with radiation, and should have expected to see bright lines; but no obvious bright lines were seen in the spectrum of the spot; what we did see was the thickening and darkening of the lines and the continuous absorption. In the case of the lines of sodium it was very marked; so that we were perfectly justified in saying that the sun-spot was really not produced by any defect of radiation, but was truly and really produced by an increased amount of absorption.

I hope to show you that we can vary the thickness of this line in precisely the same way that it is varied in the different sun-spots, and if then we examine the conditions under which we can experimentally make the line thicker, we shall in that way get some explanation of the thickening of the line in the solar spot. This experiment is rather a difficult one. We will volatilise some sodium in the electric arc and throw its spectrum on the screen. I hope to show that the absorption line is very thick to start with, and then it becomes very thin; if I give it time it will thin down gradually. What is the cause of the thickening and the thinning? It is perfectly obvious. The temperature is practically the same all the time, but we have a very considerable quantity of sodium vapour surrounding the incandescent poles in the first instance. On the further application of the heat this sodium vapour goes away by degrees, and we gradually deal with a smaller quantity, and as we deal with a smaller quantity the line thins. We therefore are justified in saying that when in a sun-spot we get the line of sodium considerably thickened, that is due to the fact that in a sun-spot there is a greater quantity of sodium vapour present.

That was the first experiment with which I am acquainted which enabled us to locate chemical phenomena in any particular part of the sun.

Now although in the year 1866 a great many people were familiar with the spots on the sun, those who had been favoured by a sight of a total eclipse, and many more who had read the accounts of total eclipses, knew that there was a great deal more of the sun than one generally sees. From the time of Stannyan, who observed the prominences at Berne, down to the year 1842, let us say, several eclipses had been observed, and very beautiful coloured phenomena had been recorded by different observers. Red things had been seen projecting round the dark moon during the time of eclipse, and although many held them to be beautful effects produced by the passage of the moon over the sun, or even clouds in the atmosphere of the moon coloured by the strange way in which the solar light then fell upon them, a larger number of people, on the other hand, insisted that these things must really belong to the sun. Now if that were so, it was perfectly clear that we should not be contented with merely observing the chemical nature of the spots.

Having the spectroscope, the things which showed thus, and which up to that time had only been observed during eclipses, would be more or less *felt*, if they were not absolutely rendered visible, by this new instrument; and for this reason: the things seen round the sun during an eclipse were not there for the instant of the eclipse only: they were always there: why did we not see them? The illumination of our own air prevented this. What was our own air illuminated by? By the sunlight. Now whereas increasing dispersion does considerably dim a continuous spectrum for the reason that it makes it extend over a larger area on the screen, it does not dim to any great extent the brightness of a line, so that by employing a considerable number of prisms we ought to be able to abolish the illumination or our air altogether, and in that way we should no longer be limited to determining merely the chemical nature of the spots, we should be equally able to determine the nature of the surrounding solar atmosphere, supposing the phenomena observed during eclipses were really solar, and not lunar or terrestrial.

I will make an experiment with the electric light. I begin with a bright continuous spectrum. We will charge the cup in the lower pole with some vapour which will give us a bright line, in addition to the continuous spectrum due to the poles, and these two things must fight it out between them. If everything goes well what should happen will be this: by first mounting one prism, then two, and then three, the continuous spectrum will be gradually enfeebled, the line keeping the same luminosity

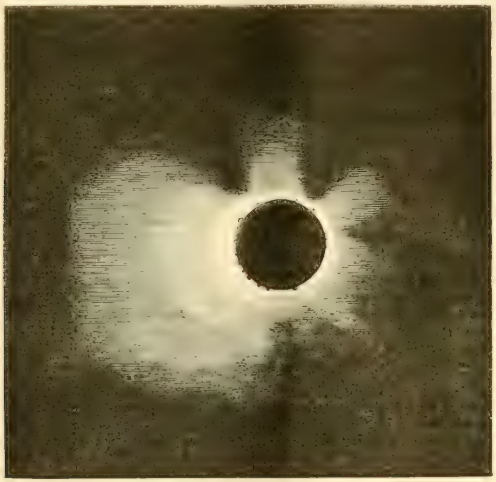

FIG. 9.—Eclipse of 1870. Photograph of the corona taken at Syracuse.

during the whole time; we shall find that relatively the line will be much brighter than the continuous spectrum by the time the experiment is concluded. That was the principle which it was suggested would enable the spectroscope to be used in making what have been called artificial eclipses.

Now if we ask what are the phenomena presented by eclipses, the sort of thing the spectroscope is called upon to observe, we shall see the very considerable advantage of the introduction of the new method. In the first place the eclipses, which are so full of the precious knowledge to be got only at that moment, are almost instantaneous, so far as each particular phenomenon is concerned; and, secondly when the duration is say, four or five or six minutes, which is a very considerable time during an eclipse, and which allows a great deal of work to be done; only a very small part of the more interesting regions of the solar atmosphere is uncovered; one part, of course, when the moon is passing over one limb of the sun, and the other when the moon in passing, liberates it, and brings it into light again. What I would draw chief attention to is the lower part of the brilliant portion seen around the dark moon. We shall have to discuss the upper portion, which is called the coronal atmosphere, or corona, on a later occasion. This mere visual reference, of course, is simply in anticipation of the chemical nature of the different strata upon which we have to operate by the spectroscope, and about which I shall have therefore to tell you in that part of the lecture which has to do with localisation. We shall thus determine, after what has been already said with regard to Kirchhoff's hypothesis as to the position of the region where the lines ought to be seen in the corona, whether during an eclipse we get anything like a justification of this hypothesis. This drawing is really a very beautiful reproduction of an eclipse. We have a round dark moon, which in this case is represented as entirely covering the sun; then these different prominences and luminosities, this wonderful set of streamers, or whatever you like to call them, which seem to veil, or to render less distinct, something else which is lying beyond them. You will see here that some of these prominences are red, and others have a yellow tinge, and that, quite independent of the colour of the prominences, we have the most exquisite coloured effects. Sometimes the radial structure is not so marked, and reveals indications of structure further away from the sun. You see wonderfully delicate tracery, lines being seen now in one part and now in another. In the photograph taken during the eclipse of 1870 we see that the luminosity of the solar atmosphere was excessively irregular, by which I mean that in one part we get a very considerable excess of light, quite independent of the sharply

defined prominences, whereas in other portions the atmosphere of the sun at the same height is not nearly so luminous. Now in none of these cases have we been able to see the thing which struck us most clearly the moment the artificial eclipse system was set at work.

The drawings of the eclipse of 1842 show us that before it was possible to observe the edge of the sun without the intervention of the dark moon there was much evidence which went to show that these red prominences or flames, these different coloured phenomena, were really, so to speak, upper crests of an almost continuous sea round the sun.

In the drawings in question, connecting the prominences,

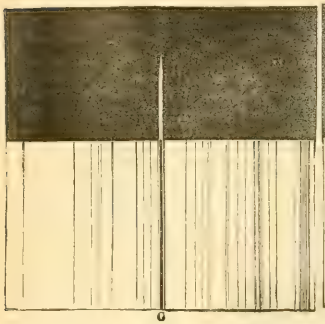

FIG. 10.—Line C (red), with radial slit.

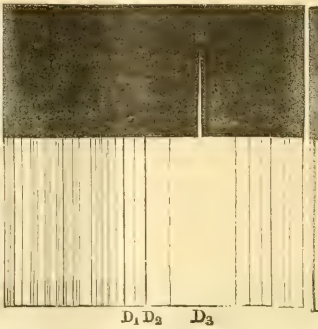

FIG. 11.—Line D_3 (yellow), with radial slit.

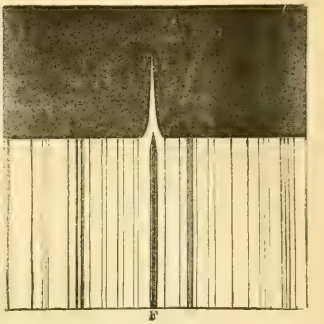

FIG. 12.—Line F (blue-green), with radial slit.

there is a fine low level of the same colour as the prominence itself. The other drawings give us those prominences after the moon had covered all the lower portion, and that is as good an indication as I can think of of the extreme difficulty of making observations during eclipses, and how important it is that one should have a method which makes us independent of them.

How then is this method carried on? It should be perfectly clear that if instead of using our slit to bisect a spot we allow the slit to fall on the edge of the sun, and then fish round it, if the method is competent to abolish the illumination of our atmosphere, to make the bright lines visible, that here and there if we catch a prominence the slit will be illuminated by the light of the prominence; and if we have the image of the sun very accurately focussed on the slit, if we know the size of the image of the sun, and if we know the length of our slit, the length of the slit illuminated by the prominence will enable us readily to determine the exact height of the prominence; so that if it should happen that there is a sort of external invisible sea round the sun usually invisible, but which this new method will pick up, that we shall get the depth of the sea sounded for us by the length of the line on the slit; and further, if that sea is not absolutely level, but if it swells here and there into waves and prominences, the slit will enable us to determine the height of the prominences. Some copies of very early drawings show exactly what is seen when a prominence is thrown on the slit, and show very well the point at which I have been driving.

Again, if we do fish round the sun in this way, and if these prominences really do give us lines, we have exactly the same method of determining the chemical nature of this exterior sea as Kirchhoff employed in determining the composition of the general light of the sun; only we have this great addition to our knowledge in this case, that whereas Kirchhoff had to suggest an hypothesis to explain the possible locus of the region which produced the lines due to the different chemical substances, we have the hard fact beneath our eyes, because if we pass over the prominence, and if it is built up of iron, let us say, then we shall see iron lines; if it is built up of calcium, then we shall see calcium lines, and so on. Now what are the facts? Here is the first observation that was recorded with absolute certainty touching the chemical nature of the exterior envelope of the sun. We find that we are dealing with the line C; and although Kirchhoff did not tell us the origin of this solar line, he showed that it was quite possible to determine the origin of the lines even if they were produced by gaseous bodies. Ångström went further, and added gaseous bodies to the subject of his investigation, and he found by using a Geissler tube he got a line in the red exactly coincident with the line C in the spectrum of the sun. When therefore we had such an observation as this, showing one of the lines produced by this external sea, coincident with the C line of the solar spectrum, we knew at once

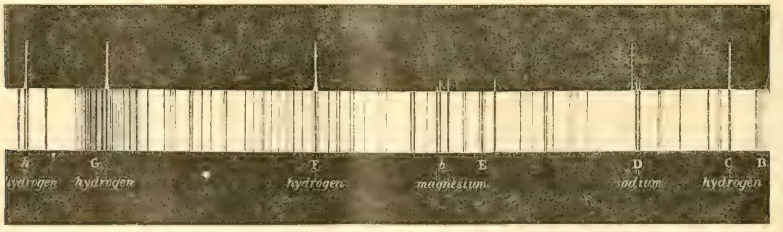

FIG. 13.—Spectrum of the sun's photosphere (below) and chromosphere (above).

that that line was produced by hydrogen. It was obvious, of course, that at once the other lines of hydrogen should be investigated. The next obvious line of hydrogen is F in the blue-green, and when the question was put to this line, in that case also it was found that the prominences gave out no uncertain sound—that the prominences were really and truly composed to a large extent of what we call hydrogen; that is to say, the spectral lines observed when we render hydrogen incandescent are identical with the spectral lines observed when we throw one of the solar prominences on the slit. It was soon found that this continuous ocean, this continuous outer shell of the sun, varied considerably in thickness from time to time, and it was

also found that other substances besides hydrogen, some of which at present we know nothing of, others of which we now think we know a great deal of, also appear side by side with the lines of hydrogen. I have already stated that other substances besides hydrogen have been determined to exist in this lower chromospheric layer. In almost all cases, however, we find that these lines are never so long as the hydrogen line, from which we gather that the magnesium sea, to take a case, is a much shallower one than the hydrogen sea. I should further add here that when the sun is moderately active and can be well

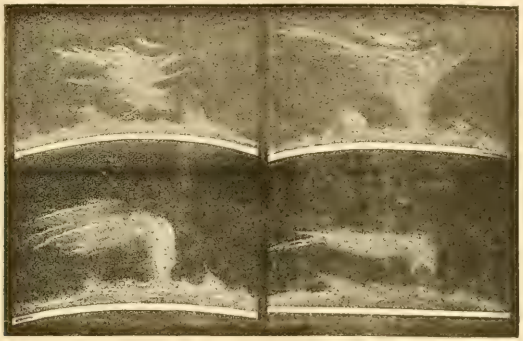

FIG. 14.—Solar prominences (Young), showing lateral currents

observed, as in a fine climate like that in Italy, this magnesium sea can be detected all round the sun, so that we have in the chromospheric layer, first of all, a sea of hydrogen with its prominences, and then at the bottom of this sea another sea of magnesium, which wells up sometimes where the prominences are strongest.

The different forms which these prominences assume are very striking. You will have no difficulty in seeing that there is really a fundamental difference between them, and that all present us with indications of movement, and these movements enable us to apply a test to the theories of the formation of spots and prominences to which Prof. Stokes referred. Prof.

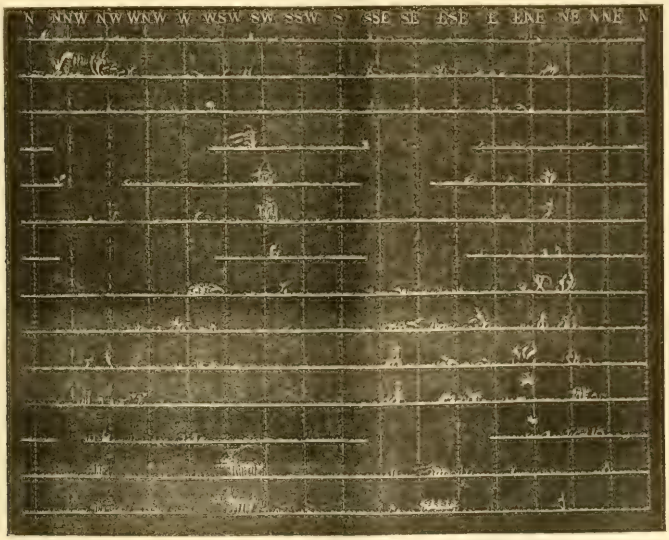

FIG. 15.—Diagram showing how the prominences are daily recorded (Respighi).

Stokes pointed out that a great many phenomena require that the sun-spot shall consist of descending currents, and that these prominences, which when we can see them are fed by the incandescent matter of the sun, should not be descending currents like those in spots, but should be ascending currents,—in fact masses of incandescent vapour shot out from the very bowels of the sun itself. The drawings, which we owe to the skill of Prof. Respigi, drawn by the simple contrivance of opening the slit after we have got the image of the prominence carefully upon it, give us a great many cases of upward move-

ment and lateral movement, sometimes excessively intense, giving indications of their being carried either to the right or to the left of the picture by horizontal currents.

Such then is a first preliminary survey of the method of observing the chemistry of the sun, not as a whole, but of each particular little bit of the sun, chosen here and there, and brought upon the slit of the spectroscope.

J. NORMAN LOCKYER

SOME OBSERVATIONS ON THE MIGRATION OF BIRDS[1]

WHILE showing some friends the astronomical observatory and accessories connected with the College of New Jersey at Princeton, on the night of October 19, 1880, after looking at a number of objects through the 9½-inch equatorial, we were shown the moon, then a few days past its full phase. While viewing this object my attention was at once arrested by numbers of small birds more or less plainly seen passing across the field of observation. They were in many cases very clearly defined against the bright background; the movements of the wings were plainly to be seen, as well as the entire action of flight. In the same way the shape of the head and the tail were conspicuous, when the bird was well focussed. As the moon had not been very long above the horizon the direction of observation was consequently toward the east, and the majority of the birds observed were flying almost at right angles to the direction in which the glass was pointed.

Here then was opportunity for the determination of two points—the kind of birds that were flying, and the general direction in which they were moving. Respecting the first, it was comparatively easy to decide as to what families the species belonged. This point was gained by observing the general shape of the birds, their relative size, the motion of their wings, and their manner of flying; that is, whether the flight was direct or undulating, by continuous strokes of the wings or by an intermittent motion of those members.

Most of the birds seen were the smaller land birds, among which were plainly recognised warblers, finches, woodpeckers, and blackbirds; the relative numbers being in the order of kinds above named. Among the finches I would particularly mention *Chrysomitris tristis*, which has a very characteristic flight; and the blackbirds were conspicuous by the peculiar shape of the tail, from which characteristic I feel most positive in my identification of *Quiscalus purpureus*. I mention such details to explain just how observations were made and conclusions arrived at.

In regard to the second point, with rare exceptions the birds were found to be flying from north-west to south-east. I do not mean that this was absolutely the direction, but that it was the approximate and general one.

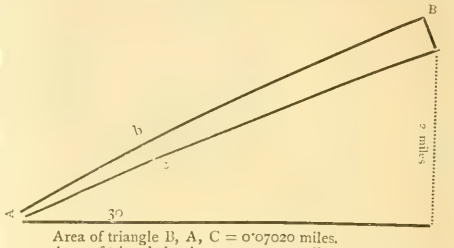
It is not within the scope of the present paper to do more than give details on two other points, namely, the estimated number of birds passing through a given space during a given time, and the height at which the birds were most abundant. For the basis of the first of these points it was necessary to note, first, how many birds passed through the field of observation per minute, and second, how near or how far distant from the glass the birds would have to be in order to be seen at all, that is to be in focus.

The height of the moon above the horizon in degrees and the two limits of the area of observation—that is how near or how far the birds noted were from the glass—supply the data for determining how high the birds seen were flying, and this, combined with the number noted as passing per minute through the field of observation, gives the basis for computing how many birds were passing through a square mile in a given time.

In this connection it may be well to specify how the two limits of observation were defined. The inferior limit, that is, the nearest point where objects could be seen with distinctness, was easily determined by the power of the glass; this is about one mile distant. The superior limit, or the most distant point, is provisionally assumed to be not more than about four miles away, on the hypothesis that the birds would not fly at a greater height than ten thousand feet. It may appear, as future observations are made, that this last limit is not correct, but the reasons for assuming such a height as the superior limit are sufficient to warrant its use in this case, for birds were observed on this same night at a late hour when the height of the moon above the horizon would make the point at which the birds were noted almost at this great elevation, viz. ten thousand feet.

I am greatly indebted to Prof. Charles A. Young for assistance in these observations, and with his aid have arrived at the conclusion that the average number of birds passing through the field of observation per minute was four and a half. Prof. Young has also kindly assisted me with the details of the problem in regard to the limits and area of the field; and the following diagram and computations are from his study of the matter.

Moon's altitude = 30°; moon's semi-diameter = 15′ 05″. The area of observation is a flat triangle = B, A, C. From this must be deducted the small triangle b, A, c, the area within a mile of the glass. The flight of the birds is thought to be nearly at right angles to the field of observation.



Area of triangle B, A, C = 0·07020 miles.
Area of triangle b, A, c = 0·00439 miles.
Therefore b, B, C, c = 0·06581 = $\frac{1}{15\cdot2}$ mile.
Distance from A to B = four miles.
Number of birds seen per minute = 4½.
Number of birds per square mile per minute = 68.

W. E. D. SCOTT

[Mr. Scott's novel and important observations definitely establish on a scientific basis several points in relation to the migration of birds that have heretofore rested almost wholly on conjecture and probability.

We have, first, the fact that the nearest birds seen through the telescope must have been at least one mile above the earth, and may have ranged in elevation from one mile to four miles. It has been held that birds when migrating may fly at a sufficient height to be able to distinguish such prominent features of the landscape as coast lines, the principal watercourses, and mountain chains over a wide area. Of this, thanks to Mr. Scott, we now have proof. It therefore follows that during clear nights birds are not without guidance during their long migratory journeys, while the state of bewilderment they exhibit during dark nights and thick weather becomes explainable on the ground of their inability to discern their usual landmarks—points that have been assumed as probable, but heretofore not actually proven.

These observations further indicate that many of our smaller birds migrate not only at night but at a considerable elevation—far beyond recognition by ordinary means of observation. A promising field is here opened up, in which it is to be hoped investigation will be further pushed, not only by Mr. Scott but by others who may have opportunity therefor.—J. A. ALLEN.]

ON THE EQUIVALENTS OF THE ELEMENTARY BODIES CONSIDERED AS REPRESENTING AN ARITHMETICAL PROGRESSION DEDUCIBLE FROM MENDELEEFF'S TABLES

THE relatively quick succession of new elementary bodies which has marked the last decade of scientific progress and which must be considered as the result of chemical research, pioneered and guided by spectroscopic study, has brought very prominently into notice Mendeleeff's most remarkable law of the periodicity of the chemical elements.

Originally published in Russian in 1871, his memoir has since been translated and reprinted by the author in the *Moniteur Scientifique* (July, 1879), and thence has been translated into some of the English journals.

TABLE I.—MENDELEEFF, *Moniteur Scientifique*, No. 451, p. 692, July, 1879.

The prevision which it has afforded of yet undiscovered elements, and the fact that the equivalent and properties of gallium correspond with those attributed by Mendeleeff to a then undiscovered metal of one of his series, gives singular importance and weight to this law, and must render it a useful, if not an indispensable guide in the research and determination of further elementary bodies and their equivalents. This point of view has been strongly insisted on by the author in the Chapters iv., v., and vi. of his memoir. In the introductory letter published in the *Moniteur Scientifique* (July, 1879), the author thus speaks of the development of the law:—

"Autrefois ce n'était qu'un schème, qu'un groupement, qu'une subordination à un fait donné, tandisque la loi périodique possède des faits, et tend à approfondir le principe philosophique qui régit la nature mystérieuse des éléments. Cette tendance est de la même catégorie que la loi de Prout, avec cette différence essentielle, que la loi de Prout est arithmétique et que la loi périodique puise son esprit dans un enchainement de lois mécaniques et philosophiques qui constituent le caractère et l'éclat de l'impulsion actuelle des sciences exactes. Elle proclame hautement que la nature des élements depend avant tout de leur masse, et considère cette fonction comme périodique."

Since in all homogeneous bodies the mass is proportional to the volume the consideration of mass leads to and admits that of volume. Therefore the basis of Mendeleeff's law involves the consideration of the volumes of the elementary bodies considered as independent atoms having necessarily limiting forms as well as characteristic weights. Although it may not be possible to fix or define rigorously at present the form of the elementary bodies or atoms when free to move, it is reasonable to admit that the spherical form is that which concords best with the nature of their movements and with their necessary freedom of action.[1]

Parting from this idea, I had been attempting, like many others, to trace out some law connecting the elementary bodies considered as having when free to act a spherical form, but abandoned the idea until I became acquainted with Mendeleeff's law and his Tables. Reverting then to the consideration of the forms and the corresponding relative volumes of the atomic elements, I remarked that a relation could be established between successive elements, as represented by their equivalents given in Mendeleeff's tables, from

[1] See Gauden, "Le Monde des Atomes," p. 32 (1873); also NATURE, vol. xxii. p. 56, "On the Physical Aspect of the Vortex-Atom Theory," by S. Tolver Preston.

the point of view of spherical volume expressed by the simple formula $\frac{4}{3}\pi\nu^3$.

Thus any two spheres being one to the other as γ^3 is to $\gamma_1{}^3$, in atomic elements γ and γ_1 are inconceivably minute, and consequently the values of the two expressions $\frac{4}{3}\pi\gamma^3$ and $\frac{4}{3}\pi\gamma_1{}^3$ for two given atomic elements if calculated would bear no comparison with the nature of the units by which the equivalents are expressed, while, however, the ratio of their volumes might be adequately represented by entire numbers of the order of the equivalents.

The law of proportionality, according to which the atoms combine, implies that the volumes of the atoms should present

[1] Approximate values of equivalents in terms of progression.

some such proportionality, consequently that for a series of atoms their volumes might be expressed by the terms—

$$\tfrac{4}{3}\pi\gamma^3 : \tfrac{4}{3}\pi m\gamma^3 ; \tfrac{4}{3}\pi n\gamma^3, \text{ &c., &c.,}$$

and therefore stand, one to the other, as the succession of terms—

$$\pi ; m\pi ; n\pi, \text{ &c., &c.,}$$

that is, be related by a series of terms in function of π.

It may be remarked that this would still be admissible if it be assumed that the forms of the atoms be that of vortex rings as argued in the very remarkable article by Mr. Tolver Preston referred to.

But if such a relation be allowed to exist it is also legitimate to admit a series of which $\frac{4}{3}\pi$, or $\frac{8}{3}\pi$, or π would be the ratio or

difference, the law of proportionality being thus still observed. Now taking the simple arithmetical progression having for difference $\pi = 3, 1416$, it furnished a series of terms which markedly concord with the series of the atomic weights or equivalents as presented by Mendeleeff's Tables, and the successive blanks occurring in the series established by him in his Tables are very approximately filled up by the succession of the terms of this progression both as regards numerical values and order of succession.

To demonstrate this Mendeleeff's Tables have been drawn out, with the addition opposite each equivalent of the corresponding approximate value in terms of the progression π.

In Table I., containing his grouping into *Typical* and *Great Periods*, there is shown the succession of the elementary bodies and their equivalents, as also the comparative concordant succession of the terms of the progression π with approximate values mostly in terms of $\frac{1}{2}\pi$.

In the Table I., or of *Periodic Series*, the blanks existing in these series as indicated by Mendeleeff are shown to be very approximately filled up by corresponding terms, in value and order of succession, of the progression π. This is markedly the case as regards the gap existing between the series 8 and 10, where are wanting *twelve terms*, which, being filled up by successive terms of the progression π, the thirteenth term, corresponding to the equivalent of Lanthanum = 180 (?) is represented in the progression π by the value $57\frac{1}{2}\pi = 180, 1164$, or approximatively by the value $57\pi = 179, 0712$.

Considering this progression of terms of π it will be found that of the sixty-five elementary bodies given in Mendeleeff's Tables the following corresponding equivalents are represented, with an approximation of less than a unit, by terms of the progression :—

H	=	1	...	$\frac{1}{2}\pi$ = 1, 0472

Tl	=	204	...	65π = 204, 2040
Pb	=	207	...	66π = 207, 3450

Such a concordance must be taken as some proof of the reality of a certain correspondence between the values of the equivalents and those of the terms of the progression π.

It is fully admitted that the equivalents are but relative, both as regards their number and their numerical values, to the forces which the present state of chemical analysis can bring to bear on matter, and admitting the existence of a law of progression by which the equivalents may be connected, such a progression should as a matter of necessity differ both as regards the number of representative terms and their values from the present received succession and numerical values of the equivalents, and consequently show discordances in certain places and approximate concordances in others; such is shown by the terms of the progression π.

J. P. O'REILLY

May, 1880

BIRDS OF THE SOLOMON ISLANDS

IN a paper "On the Birds of the Solomon Islands," by E. P. Ramsay, F.L.S., &c., Curator of the Australian Museum, Sydney, read before the Linnean Society of New South Wales, February 23, 1881, the following new birds were described :—

1. *Graucalus elegans*, sp. nov.—A species allied to *G. hypoleucus* of Gould, but differing in its smaller size, whiter under-surface, broad jet black band on loreal region, extending below the eye, and in having ashy grey shoulders.

2. *Piczorhynchus Richardsii*, sp. nov.—A remarkably distinct species, with the body and the wings and tail above black, ossified nape, and hind neck white, head and throat black, chest and remainder of the under surface chestnut; this species comes from the Island of Nyi, and has been named in compliment to Lieut. Richards, R.N.

3. *Myzomela Tristrami*, sp. nov.—A jet black myzomela of large size, the bill strong and yellow, with end black, bases of the inner webs of the quills below ashy. This species is allied to, but distinct from, *M. nigra*, *M. Forbesii*, *and M. pammelana*.

4. *Mygomela pulcherrima*, sp. nov.—This fine species has the whole of the head, neck, chest, breast, and sides of the body and flanks, the interscapular region, rump, and upper tail coverts of a rich deep crimson, the remainder of the plumage black. The extent of the scarlet on the flanks and breast is greater than in either of the allied species *M. cardinalis* and *M. nigriventris*.

5. *Zosterops* (*Tephras ?*) *olivaceus*, sp. nov.—In this genus there is no trace of white round the eye, and the bill has quite a different contour than that of any species of the genus *Zosterops*. The first and sixth primary quills in this species are equal, and the third is equal in length to the fourth. The general colour above is a uniform dull brown washed with olive, inclining to smokey brown on the head, inner webs of the quills below margined with white, under surface light ashy brown, almost white on the abdomen, length about five inches.

6. *Nasiterna fiuschii*, sp. nov.—A very distinct species of a uniform grass-green tint, paler on the abdomen, under tail coverts yellow, length 3·8 inches.

The paper contains notes on six or eight other species of interest and a fine collection of Solomon Island birds were exhibited—about fifty species.

OUR ASTRONOMICAL COLUMN

THE VARIABLE STAR χ CYGNI.—A maximum of this variable should now be close at hand. Prof. Winnecke assigns it to July 31, rather later than the average period of the last few years would give it. Its brightness at maximum has varied during the present century from 4m. to a very little above 7m. In vol. vi. of the Bonn Observations, Argelander has given nine observations of the position of this star, about which there has been so much and unnecessary confusion. Its place for 1880·0 is in right ascension 19h. 45m. 57·33s., declination 32° 36′ 42″·1. A comparison of Lalande's observation in 1793 with Argelander's shows that there is no appreciable proper motion. The variability of χ Cygni was discovered in 1686 by Kirch, whose first observed maximum is dated November 28, 1687.

COMET 1881 *b*.—It appears this comet was detected at Sydney as early as May 22, so that we may yet receive observations from the Australian observatories made nearly a week before the first of those made at Rio Janeiro. The orbit, founded upon post-perihelion places, which we published last week, gives the comet's place on May 22 at 10 p.m. at Sydney in right ascension 4h. 58·5m., declination 35° 33′ S., and at this time the comet was distant from the earth 0·772 of the earth's mean distance from the sun. M. Cruls' first position, deduced from the observations at Rio is as follows :—

M.T. at Rio.	R.A. h. m. s.	Decl. ° ′ ″
May 29·27980 ...	5 2 3·8 ...	−31 15 24·9

The comet was nearest to the earth about midnight on June 19, when its distance was 0·283.

The ephemeris subjoined is for Greenwich midnight :—

	R.A. h. m.	N.P.D. ° ′	Log. distance from the Earth.	Sun.
July 22 ...	11 44·2 ...	8 5·0 ...	9·9290 ...	0·0065
23 ...	11 55·5 ...	8 13·5		
24 ...	12 5·9 ...	8 22·7 ...	9·9479 ...	0·0173
25 ...	12 15·5 ...	8 32·4		
26 ...	12 24·5 ...	8 42·5 ...	9·9657 ...	0·0281
27 ...	12 32·9 ...	8 52·9		
28 ...	12 40·7 ...	9 3·4 ...	9·9825 ...	0·0388
29 ...	12 48·0 ...	9 13·9

4 ...	13 24·0 ...	10 17·2		
5 ...	13 29·2 ...	10 27·4 ...	0·0404 ...	0·0800
6 ...	13 34·3 ...	10 37·4		

Comet 1881 *c*.—Telegrams from the Smithsonian Institution at Washington notify the discovery of a comet at the Observatory of Ann Arbor, by Mr. Schäberle, apparently on July 16; it was situate, according to the telegrams, nearly in the right ascension of Capella in 48° declination (or ? 38°).

Near approach of Venus to 107 Tauri.—Prof. Winnecke has circulated a note in which he suggests a method of determining the solar parallax from observations of this planet, when it approaches or occults a fixed star. We refer to the note at this time, only to draw attention to a close approach of the planet to 107 Tauri, a star of 6·5m. on the morning of July 24. According to a calculation by one of Prof. Winnecke's pupils the star will be occulted, but there appears to be some mistake here. Taking the star's place from the Greenwich Catalogue of 1864 and the Radcliffe Observations 1870-75, its apparent position will be R.A. 5h. 1m. 51·33s., Decl. +19° 42′ 15″·1, and at conjunction in R.A. July 23 at 20h. 26m.·2 G.M.T., the geocentric difference of declination (Venus-star) is 28″·7; this difference is reduced by the effect of parallax at Greenwich to 22″·9, and Wichmann's value of the semi-diameter of the planet being 10″·8, it appears neglecting tabular error of place, that at conjunction in right ascension, the south limb of Venus will be 12″ north of the star.

[Since the above was in type Dr. Gould's observations of the great comet at Cordoba have been received; they show that at the end of May the elements upon which our ephemeris is founded may give the comet's position with errors of + 1′·0 in R.A., and + 3′·8 in declination.]

Govi.

SOCIETIES AND ACADEMIES

London

Geological Society, June 22.—R. Etheridge, F.R.S., president, in the chair.—Thomas Hart and David William Jones, Coronel, Chili, South America, were elected Fellows of the Society.—The following communications were read:—Description of a new species of coral from the Middle Lias of Oxfordshire, by R. F. Tomes, F.G.S. The species of coral described in this paper was referred by the author to the genus *Thamnastræa* and the sub-genus *Synastræa*, under the name of *Thamnastræa Walfordi*, in honour of its discoverer, Mr. E. A. Walford. The specimen was from the *Spinatus*-beds of the Marlstone, at Aston-le-Walls, Oxfordshire. Like *Thamnastræa Etheridgei*, previously described by the author (*Q. J. G. S.* xxxiv. p. 190) from the Middle Lias of Oxfordshire, this species presents the same sub-generic characters as *T. arachnoides* of the coral rag of Steeple Ashton; and the author remarks upon the fact that the only species known from the English Lias resemble corallian rather than Inferior-Oolite forms.—Note on the occurrence of the remains of a Cetacean in the Lower Oligocene strata of the Hampshire basin, by Prof. J. W. Judd, F.R.S., Sec.G.S. With a note by Prof. H. G. Seeley, F.R.S., F.G.S. The author referred to the rarity of remains of marine mammalia in the Lower Tertiaries of Britain, the only recorded species being *Zeuglodon Wanklyni*, Seeley, from the Barton clay. The single specimen in his possession was obtained at Roydon, about a mile and a half north of Brockenhurst, where the beds exposed in the brickyard consist of sandy clays crowded with marine fossils, and resting upon green freshwater clays, with abundance of *Unio Solandri* belonging to the Headon series. The author briefly referred to the question of the horizon of these deposits, which he regards as belonging to the same great marine series as the beds of Brockenhurst and Lyndhurst, which he holds to be Tongrian or Lower Oligocene. The Cetacean vertebra obtained by Prof. Judd was stated by Prof. Seeley to be a caudal vertebra, probably the eighth, but not later than the twelfth, of a species belonging, or closely related to the genus *Balænoptera*, and especially approaching *Balænoptera laticeps*, a species of the North Sea which appears to range to Japan. Prof. Seeley regarded it as representing a new species, which he named *Balænoptera Juddii*.—Descrip-

tion of a peat-bed interstratified with the boulder-drift at Oldham, by G. H. Hollingworth, F.G.S. The author described a deposit of peat interstratified with boulder-drift, exposed in a railway-cutting at Rhodes Bank, Oldham. The depth of the section was only 14 feet, and it showed :—

1. Soil	8 to 10 inches.
2. Boulder-clay, with beds and strings of peat	2 to 6 feet.
3. Main bed of peat, containing mosses, exogenous stems, and beetles	2 in. to 1 ft. 9 in. (average 15 in.).
4. Fine blue clay (floor)	2 inches to 1 foot.
5. Current-bedded coarse sand and fine gravel	4 inches to 2 feet.
6. Boulder-clay.	

The mosses in the peat are of northern type.

Silurian uniserial *Stomatoporæ* and *Ascodictya*, by G. R. Vine, communicated by Prof. P. Martin Duncan, F.R.S. For the genus *Stomatopora* the name *Alecto* has priority ; but as that had previously been applied to a member of the class Echinodermata, the author preferred the later name. Species of the genus have also been described under the generic name *Aulopora*. The author has received from Mr. Maw more than two hundred weight of washed *débris* of Wenlock shale, about thirty pounds of which, from twelve localities, he has examined. It contains a moderate amount of Polyzoan remains, generally water-worn. The author described the following species :—*Stomatopora inflata* and *dissimilis*, *Ascodictyon stellatum* and *radians* (with a variety *silurienne*), and discussed the characters of the genera.—Note on the diamond-fields of South Africa, by E. J. Dunn, communicated by Prof. Ramsay, F.R.S. The passes or necks of decomposed gabbro, &c., at the Kimberley, Bultfontein, and other diamond-mines have now been excavated to a considerable depth, and have allowed excellent sections of the sedimentary beds through which they have broken to be examined. These are generally but little disturbed, and may be traced over an area of many square miles. Immediately beneath the surface are, generally, yellowish shales, with remains of small Saurians : and beneath these a mass, certainly more than a hundred feet thick, of black carbonaceous shales, with occasional thin bands of coal. It is found that the diamonds are more abundant and of better quality when the level of the black shales is reached. It seems, therefore, not improbable that the carbon requisite for the formation of diamonds was obtained from these shales. Some other points of minor interest were also noted in this paper.—On a new *Comatula* from the Kelloway Rock, by P. H. Carpenter, M.A., Assistant Master at Eton College, communicated by the President. The specimen, to which the author's attention was called by R. Etheridge, jun., is in the national collection ; he proposes for it the name *Actinometra calloviensis*. The specimen is from the Kelloway rock, of Sutton Benger ; the whole diameter is 15 mm. ; diameter of centrodorsal 6 mm. Three species of this genus are already known from the British Jurassic rocks ; two are only known from their centrodorsals, which are each different from that of *A. calloviensis*. The third is *A. cheltonensis*, from the Inferior Oolite, known only by its radials and basals, which are different from those of the present specimen. To this *Antedon Picteti*, from the Valangian of the Continent, has some resemblance. It is, however, a true *Actinometra*, differing chiefly from existing forms in retaining its primary basals without their having undergone transformation into a rosette.—Descriptive catalogue of Ammonites from the Sherborne district, by Sydney S. Buckman. Communicated by Prof. J. Buckman, F.G.S., F.L.S., &c. In this paper the author gave a list of the Ammonites from the Inferior Oolite of the neighbourhood of Sherborne, in which he enumerated about forty-seven species, and stated that he had about fifty more which appear to be undescribed ; fully one half have the mouth-termination perfectly preserved. The author indicated the zones into which the rocks furnishing these Ammonites could be divided, as shown at Oborne, near Sherborne, at Wyke Quarry, and at Bradford Abbas, and indicated the characteristic fossils of each ; he also gave the principal synonyms of the species referred to, and discussed some of their characteristic peculiarities.—The next meeting of the Society will be held on November 2, 1881.

Entomological Society, July 6.—Mr. H. T. Stainton, F.R.S., president, in the chair.—One new Member and one Subscriber were elected.—Mr. W. L. Distant exhibited the sexes of *Morpho Adonis*.—Miss E. A. Ormerod exhibited some elm-leaves bleached by the attacks of a Coleopterous larva ; and larvæ of a species of *Dolerus* and of *Charæas graminis*, feeding on grass.—Rev. E. A. Eaton exhibited drawings by Mr. A. T. Halleck of the nymphs of various *Ephemeridæ*.—The Secretary read the report of the Committee appointed at the last meeting to inquire into the history of an insect found feeding on the eggs of locusts in the Troad. It proved to be a dipterous insect apparently belonging to the *Bombyliidæ* ; and specimens were exhibited by Sir S. S. Saunders.—The following papers were then read :—Mr. F. Moore, descriptions of new Asiatic diurnal *Lepidoptera*.—Mr. D. Sharp, on the species of the genus *Euchroma*.—Mr. J. W. Douglas, observations on the species of the homopterous genus *Orthezia*.—Mr. A. G. Butler, on the Lepidoptera of the Amazons collected by Dr. Trail during the years 1873-1875. Part iv. Geometrites.—Baron Osten-Sacken, note on the larva of Nycteribia.—Mr. W. F. Kirby, notes on new or interesting species of *Papilionidæ* and *Pieridæ* collected by Mr. Buckley in Ecuador.

Edinburgh

Royal Society, June 6.—Sir Wyville Thomson, vice-president, in the chair.—Prof. H. Alleyne Nicolson, in a paper on the structure of the skeleton in *Tubipora*, and on the relations of the genus to *Syringopora*, argued that the similarity between the skeletons of these genera was only apparent, and that careful and minute microscopic study proved them to be built up in very different ways. In the former genus the skeleton is porous and made up of fused spicules. There are no tabulæ, and the axial tube, when present, seems to be simply the calcified wall of the body cavity, coming into contact with the external walls only at the nodes which mark the stages of growth. In the Syringopora again the skeleton is not porous, while there are true septa and funnel-shaped tabulæ which give rise to an axial tube.—Prof. Tait communicated a note by Mr. A. P. Laurie on an iodine battery, whose great merit is that it combines the simplicity of a single fluid cell with an electromotive force practically constant. Carbon and zinc plates dip into a solution of iodine in iodide of zinc, the iodine preventing polarisation. The zinc should not be amalgamated, and should be removed from the solution when the cell is not working. As tested by a quadrant electrometer, the electromotive force was very approximately one volt, and was hardly diminished, even after half an hour's short-circuiting.—In a note on chemical affinity and atomicity Mr. W. Durham brought forward certain objections to the generally-accepted theory of atomicity, arguing that there was no sufficient ground for assuming that one atomicity of a given element was saturated by one atomicity of another element in the compound, that this assumption led to the necessity of giving to certain elements different atomicities, and that it was more rational to suppose a given atomicity distributed among several of the like constituents of the compound.—Sir Wyville Thomson communicated a paper on the physical and biological conditions of the channel between Scotland and the Faröe Islands. A series of soundings taken last summer had proved the existence of a narrow ridge running across this channel and flanked on both sides by deep water. Down to a depth of 260 fathoms (the depth of the ridge) the ocean water on both sides of this ridge was at much the same temperature, while at lower depths the water to the north-east was markedly colder than that to the south-west ; thus at 450 fathoms the temperatures of these regions were respectively 30°·5 F. and 47°·2 F. The characteristic fauna of these regions showed a corresponding diversity, that of the north-east basin being similar to the Scandinavian fauna, and Arctic in character, that of the south-west being similar to the fauna found in the warmer waters all over the ocean bed. Many new forms were discovered in both of these regions.

June 20.—Prof. Maclagan, vice-president, in the chair.—Prof. Chrystal, in a note on Sturmian functions, gave a simple demonstration of a theorem of Joachimsthal, expressing a class of these functions as the successive minors of a symmetrical determinant.—Dr. Herdman communicated Part iv. of the Preliminary Report on the *Tunicata* of the *Challenger* Expedition.—Mr. D. B. Dott gave a short account of a series of experiments which he had made on comenic acid and its salts, which he regarded as establishing its dibasic character.—Dr. Macfarlane read a paper on Morgan's systems of consanguinity and affinity, which he had examined with the help of his analysis of relationships. The paper consisted of two parts, the first being a criticism of the tables of data, the second of an explana-

tion of the so-called classificatory methods. The classification proceeds according to difference of generation, and is merely one mode in which the relationship ideas may be expressed in words. Mr. Morgan's hypothesis of a consanguine and of a Panalu'an family are contradicted by the data which they are introduced to explain.—Prof. Tait communicated a note on a proposition in the theory of numbers.

PARIS

Academy of Sciences, July 11.—M. Wurtz in the chair.—The following papers were read:—On the formation of the tails of comets, by M. Faye. A reply to M. Flammarion. The tail is not rigidly connected with the nucleus. The repellent force is proportional to the surfaces, is weakened by interposition of a screen, is not propagated instantaneously, and varies in inverse ratio of the square of the distance.—Theory of plane flexion of solids and consequences relating to construction of astronomical telescopes, and to their regulation, getting rid of deviations of the optic axis due to flexion, by M. Villarceau.—On the velocity of propagation of explosive phenomena in gases, by M. Berthelot. The experiments were with mixtures of hydrogen and oxygen and of carbonic oxide and oxygen (2 vols. to 1). These were placed in a long iron tube (open or close, fixed in various positions, &c.), and were inflamed with an electric spark; the passage of the wave was measured by an electric method. The velocity was in general about 2500 m. per second. Explosive phenomena are more complex than a simple motion of translation or even than the propagation of a sound wave.—Reply to M. de Lesseps on M. Roudaire's project, by M. Cosson.—On the borings made in strata to be traversed by the Panama Canal, by M. de Lesseps. The strata of large section will offer sufficient consistency for formation of talus, while not preventing the resistance of hard rock.—Study in experimental thermodynamics on steam-engines, by M. Ledieu.—Photography of the spectrum of comet *b* 1881, by Dr. Huggins. M. Berthelot thought the spectra rendered probable the electric origin of the proper light of comets.—Influence of phosphoric acid on phenomena of vegetation, by M. de Gasparin.—Remarks on the accidents caused by use of sulphide of carbon in treatment of vines in the South of France, by M. Cornu.—Shocks of an earthquake at Gabes on June 13 were reported.—On the comet of 1881 observed at the Imperial Observatory of Rio de Janeiro, by M. Cruls.—Observations on the same comet at Algiers Observatory, by M. Trépied.—Further observations by M. Wolf and by M. Thollon (See page 261).—Attempt at explanation of the tails of comets, by M. Ficart. A comet, consisting of gaseous matter and luminous ether, appears, at a distance from the sun, in spheroidal form (the luminous ether being then invisible). But on nearing the sun the luminous ether of that star repels the luminous ether of the comet; hence the tail.—On the polarisation of the light of comets, by M. Prazmowski. The comet is shown to reflect solar light abundantly.—New method of determining certain constants of the sextant, by M. Gruey.—On Kleinian groups, by M. Poincaré.—On a general means of determining the relations between constants contained in a particular solution, &c. (continued), by M. Dillner.—On the three centrifugal axes, by M. Brassinne.—On the absolute measurement of currents by electrolysis, by M. Mascart. By careful experiment he finds the intensity of the current capable of producing in one second the electrolysis of 1 equiv. of a substance expressed in milligrammes is equal to 96·01 w., or say 96 webers.—On the reality of kinematic equivalence in undulatory optics, by M. Crouillebois. M. Cornu made some remarks.—On the chlorides of iron, by M. Sabatier.—On the oxychlorides of strontium and of barium, by M. André.—Experimental researches on decomposition of picrate of potash; analysis of products, by MM. Sarrau and Vieille.—On decipium and samarium, by M. Delafontaine. He reserves the name *decipium* for the radical of the earth having an equivalent of about 130; *samarium* for the other metal (in samarskite) whose absorption spectrum was described by M. Lecoq. (The equivalent of samarine is probably under 117.)—Action of peroxide of lead on alkaline iodides, by M. Ditte.—On ethers of morphine considered as phenol, by M. Grimaux.—Researches on tertiary monamines; III. Action of triethylamine on ethers with hydracids of secondary and tertiary alcohols, by M. Renoul.—On cyanised camphor, by M. Haller.—On the composition of hydrosulpbite of soda and of hydrosulphurous acid, by M. Bernthsen.—Two facts relating to decilene (oil of turpentine), by M. Maumené.—On *viscose*, or the gummy substance of viscous fermentation, by M. Béchamp.—Determination of urea with the aid of titrated hypobromite of soda, by M. Quinquaud.—Researches on animal heat, by M. d'Arsonval. By direct calorimetry he proves the great absorption of heat by the egg in incubation during the first day (a fact otherwise proved by M. Moitessier). Oxygen is abundantly absorbed and carbonic acid emitted. During sleep or complete rest, animals absorb much oxygen and make little heat, the emission of carbonic acid varying slightly. The author hardly ever found agreement between the heat measured directly and the heat calculated from respiratory combustions; this is because organic combustion is of the order of fermentation. The chemical method gives the sum; direct calorimetry the difference. The two methods should be combined.—Action of maté on gases of the blood, by MM. d'Arsonval and Couty.—Absorbed by the stomach or the veins, maté diminishes the carbonic acid and the oxygen of arterial and venous blood enormously (sometimes a third or a half of the normal quantity).—On the seat of cortical epilepsy and of hallucinations, by M. Pasternatzky. Cortical epilepsy is really what the name implies. The hallucinations he produced in a dog with absinthe he attributes to excitation of the sensitive sub-cortical centres by that substance.—On the alterations of the cutaneous nerves in pellagra, by M. Dejerine.—On venous circulation by influence, by M. Ozanam. Among the various causes of progression of blood in the veins is an important influence exercised on each vein by the artery associated with it. The vein-walls experience a rebound from the arterial movements.—On the structure of the oothecæ of Mantes, and on the hatching and first moulting of the larvæ, by M. Brongniart.—Chemical researches on the product of secretion of the ink-bag of Cephalopoda, by M. Girod.—On the synchronism of the marine carboniferous fauna of Ardoisière (Allier), and the anthraciferous fauna of Roanuais and Beaujolais, by M. Julien.—M. Laurey noted, about the comet, that the sunlight illuminated only the left part, leaving the right dark—a true cometary phase.

VIENNA

Imperial Academy of Sciences, June 23.—L. T. Fitzinger in the chair.—L. T. Fitzinger, examination of some species which were till now incorporated with the species *Ursus arctos*.—F. Steindachner, contributions to the knowledge of African fishes (contains a description of a new species of *Sargus* from the Galapagos Islands).—Joh. Mayer, on the trajectory of the 1880 *b* comet.—Max. Margules, on the motions of viscous liquids and on the figures of motion.—F. Ströhmer, on the occurrence of ellagic acid in pine-bark.—Ernst Schneider, a sealed packet (experiment on the construction of high-power telescopes).—MM. Neumayr and Emil Holub, on the fossils at the Uitenhage formation in South Africa.—M. Neumayr, studies on fossil Echinodermata.—V. v. Lang, on the coefficient of refraction of concentrated solutions of cyanine.—L. Haitinger, on the occurrence of malic and citric acid in *Chelidonium maius*.—Dr. T. Puluj, a sealed packet (without inscription).

MISS GORDON CUMMING'S "FIJI"

At Home in Fiji. By C. F. Gordon Cumming. In Two Volumes. With Map and Illustrations. Second Edition. (London: Blackwood and Sons, 1881.)

MISS GORDON CUMMING is a most indefatigable traveller, daunted by no hardships or discomforts, ready to push her way anywhere, and as happy and contented almost in a Fijian dwelling as if at home. She has travelled over most of the world, and being a most skilful draughtswoman, has, like Miss North, brought back with her a vast series of large coloured sketches of all the principal points of interest visited by her. Whilst however Miss North's fine and most instructive collection is executed in oils, the author of the present work sketches in water colours. Miss Gordon Cumming's drawings are very beautiful and, as all those who have been fortunate enough to see them can testify, extremely faithful representations of the scenes which they depict, and she has sketched some of the most interesting scenes existing, such as the hot springs and geysers of New Zealand, the ruined ancient cities of Ceylon, the summit of Adam's peak at sunrise, with the curious coloured edged shadow then cast by the mountain, and the ever-surging lava lakes of Kilauea in Hawaii. She went to Fiji as companion to Lady Gordon on the appointment of Sir Arthur Gordon as first governor of the islands in the beginning of 1875. She stayed there more than a year and a half, seeing a great deal of the people and constantly travelling in various parts of the group. The present book is a bright and pleasant account of what she saw and did. She made a large series of sketches, and seven of these, reproduced by the autotype process, illustrate the present work. Any one who knows Fiji will at once recognise the minute accuracy with which they represent the scenery of that beautiful group, though they are, of course, but feeble substitutes for the coloured originals.

It is pleasing to learn that the Wesleyan missionaries, to whom the entire credit of the civilisation of the Fijis is due, expressed their satisfaction at the annexation when it actually took place. They certainly had very serious apprehensions as to its effect on the well-being of the native population some years before, when the matter was only under consideration. It is a pity indeed that the hoary old cannibal Thackombau was taken down to Sydney to bring back the measles to his islands and thus destroy a third of the population. The difficulties of the problem with which Sir Arthur Gordon had to deal at the outset of his governorship were greatly enhanced and complicated by the effects of this terrible mishap. It is pleasing to learn that old Thackombau is still as fond of his bible as when we saw him seven years ago; he cannot read it, apparently, but, as our authoress tells us, "it makes him feel so good." No doubt if he could read some of the battle scenes in Kings he would feel better still.

Fijians seem to be rather a failure as domestic servants.

"Day after day you must show them exactly how everything is to be done, and may be certain that each time it will be done wrong, and that the moment your back is turned they will proceed to bruise up a bit of tobacco in a banana leaf and deliberately smoke their cigarette before touching the work you have given them. Probably they will follow you to ask where the matches are, and the only answer to any remonstrance is 'malua' (by and by), a universal principle which is the bane of Fijian life. They are honest, though sometimes they cannot resist borrowing large English bath towels, which make most tempting *sulus* (kilts), and nice cambric handkerchiefs are a tempting covering for carefully dressed hair. It would be right and proper that they should use things belonging to their own chiefs, so we need not wonder that they cannot always discriminate."

The authoress was especially struck by the absence of flowers in the island, and describes this fact as all the more striking to her after a vogage direct from Australia (Sydney), where the whole country was aflame with blossom. She walked day after day till she was weary without finding as many flowers as would fill a small vase. She bears testimony, on the other hand, to the profusion of ferns. Mr. Wallace has dwelt in his work on "Island Life" on the causes to which this absence of flowers in oceanic islands is due. Miss Gordon Cumming's testimony on the matter is interesting.

Sir Arthur Gordon was punctilious in matters of native etiquette, and constantly attended kaava yangona drinkings. It is quite new to us to learn that the process of preparing kaava by chewing in Fiji was imported from Tonga, and that in the interior the old custom of grating the pepper root survives. If this statement is correct the process must have come from Tonga some time ago, for the root is only grated there now by order of the missionaries, who introduced this method in order to prevent the spread of disease occurring in consequence of the chewing. As chewing was the method adopted originally all over Polynesia, it would be strange if Fiji had been an exception in the matter.

Some remarks are made in the work on the so-called *orthodox* mode of Fijian spelling, that is to say, the strange mode of spelling which the missionaries have thought fit to adopt. According to this spelling Thackombau is spelt Cacobau, *c* being used instead of *th*, and an *n* sound, which invariably occurs before *d*, *g*, and *q*, being omitted in the spelling. There seems nothing to be gained and all to be lost by this arrangement, a mere going out of the way to create a difficulty, unless indeed it be a device to prevent the Fijians when taught to read and write Fijian from being able to read English.

Amongst the crowds of plantation labourers from all parts of Polynesia the authoress specially mentions the Tokelau islanders, "with their long straight hair, large dark eyes, and sallow faces." There is something very peculiar in the Tokelau race, and we believe there is much of importance yet to be made out with regard to it. Every visitor to Levuka cannot help being struck at once by the very marked difference in appearance between the Tokelau men and women and all other Polynesians and Melanesians taken together amongst the labour population of the place. They alone of all the islanders can be recognised in any crowd at once by any one without any fear of mistake. They have a Mongolian look, and we cannot help thinking there is something remarkable in their origin, although their language is very closely allied to Samoan.

A lively account is given of a Palolo fishery, which

the authoress was lucky enough to witness. There is a great deal in the book about cannibalism. A representation of one of the well-known so-called cannibal forks adorns the covers of the books. These forks are so much prized by visitors as curiosities that we caught a boy on the Rewa River making a couple of trade ones, and have got one of them now in our possession. It is a mistake to suppose that they were never used for eating any food except long pig (*hokola*). A young chief of one of the mountain tribes was asked whether women joined practically in the delights of cannibal feasts: he said, "I'd like to see the woman that would not eat her full share." He bore testimony to the superiority of long over short pig as food.

An interesting account is given of one of the native missionary meetings and of the set dances (*meke*) which take place at them. One of the most curious dances described is one representing a tide rising on a reef:—

"The idea to be conveyed is that of a tide gradually rising on a reef, till at length there remains only a little coral isle, round which the angry breakers rage, flinging their white foam on every side. At first the dancers form in long lines and approach silently, to represent the quiet advance of the waves. After a while the lines break up into smaller companies, which advance with outspread hands and bodies bent forward to represent rippling wavelets, the tiniest waves being represented by children. Quicker and quicker they come on, now advancing, now retreating, yet, like true waves, steadily progressing and gradually closing on every side of the imaginary islet round which they play or battle after the manner of breakers, springing high in mid-air, and flinging their arms far above their heads to represent the action of spray. As they leap and toss their heads, the soft white *masi* or native cloth (which for greater effect they wear as a turban with long streamers, and also wear round the waist, whence it floats in long scarf-like ends) trembles and flutters in the breeze. The whole effect is most artistic, and the orchestra do their part by imitating the roar of the surf on the reef—a sound which to them has been a never-ceasing lullaby from the hour of their birth."

The Fijians are, with little doubt, the best dancers in the world, and it is interesting to contrast their condition in this respect with that of ourselves, amongst whom dancing has degenerated in proportion as music has become highly developed, until it may almost be said that practically only one dance survives amongst us, and that a monotonous performance, which, by a very slight revival, is just being promoted from two to three steps. Yet Englishmen can dance when the Fijians teach them All the dancers were of course fantastically painted.

"We were chiefly puzzled and attracted by one very fine fellow, all painted black, with a huge wreath and neck garland of scarlet hybiscus and green leaves, and rattling garters made of many hanging strings of large cockle-shells, and the usual *liku* (a sort of kilt or waist drapery) of fringes of coloured pandamus leaves. Of course he carried a club, and was barefooted. This man distinguished himself greatly, and afterwards acted the part of a huge dog in a dance where all the children appeared on all fours as cats. Eventually we discovered him to be a European known as Jack Cassell."

When the short war with the Kai Volos, the till then unsubdued cannibals of the mountainous interior of Viti Levu, took place, all the chiefs sent small detachments of fighting men to the governor to help in the fight. One hundred and fifty such men came from Mbau. They marched up on to the governor's lawn armed with Tower muskets, and performed the wildest war *meke*, ending with unearthly yells. They then advanced two or three at a time, brandishing their weapons, and trying who could make the most valiant boast concerning his intended progress. One cried, "I go to the mountains, my feet shall eat the grass." This was to express his eager speed. Another, "I long to be gone, I crave to meet the foes. You need not fear; here is your safeguard." "This is only a musket," cried another, "but I carry it." Said the next, "We go to war; what hinders that we should fill all the ovens?"—a hungry cannibal ally that. One company which advanced with more stately gait, "This is Bau, that is enough."

It makes our legs tingle now a little to hear that a boy was torn and killed by one of the freshwater sharks, *Carcharias Gangeticus*, inhabiting the great Kewa River in Viti Levu during Miss Gordon Cumming's stay there, for we spent most of one night in and out of the water of the river not so long ago, pushing off our boat as she grounded constantly with the falling tide. We trusted to the sharks in the upper part of the river being only small ones, but the boy was killed at a distance of thirty miles from its mouth. The authoress had bathed in the river herself occasionally. She does not seem to be aware that the shark in question regularly inhabits the fresh water.

We cannot follow the authoress in her account of Fijian feasts, Fijian puddings—twenty-one feet in circumference—Fijian weddings, where the bride's dress is so cumbrous that it is carried by her friends to the church and put on outside on the shore under the cocoanut trees; of the hot springs of Savu Savu, used for cooking and for getting rid of superfluous babies; of the details of the process of making the beautiful Fijian pottery, and many other matters on which we would wish to dwell.

The book loses somewhat in general effect from being retained in the form of a series of letters, an arrangement always somewhat irksome to the general reader. Perhaps also for the taste of many there is a little too much about the missionaries in the book; but as there were 900 Wesleyan chapels in the islands, and, as said before, the missionaries have brought about all the civilisation existing, they necessarily must appear a good deal in such a work. They seem sometimes to excite the admiration of their flock in a rather dangerous direction. An old ex-cannibal crept close to one who apparently is somewhat stout, "and then, as if he could not refrain, he put out his hand and stroked him down the thigh, licking his lips, and exclaiming with delight, 'Oh! but you are nice and fat.'" We always thought that Fijians, like cannibals elsewhere, had found out by experience that white men are comparatively poor eating.

We thank Miss Gordon Cumming much for her very interesting book, but before we close this notice we have one bone to pick with her. She falls into the really unpardonable popular error of talking of coral insects, and even talks of the parrot-fish extracting from the coral the insects on which it feeds. We hope she will learn before a third edition of her work appears that the animals, the skeletons of which are commonly called corals, are no more like any insects than a whale is to a blue-bottle. The fact is, coral skeletons look a little like honeycomb, and so we suppose the popular delusion will flourish for ever.

OUR BOOK SHELF

Practical Botany for Elementary Students. Introductory to the Systematic Study of Flowering Plants. By D. Houston, Science Master, South London Middle-Class School Association. (London: W. Stewart and Co., 1881.)

THIS book differs from Mr. Bettany's (vol. xxiv. p. 235) in being less general in its treatment. It is in fact a series of studies of the coarse anatomy of a number of common plants much on the plan first given in Huxley and Martin's "Elementary Biology." Each study is followed by a technical description, notes on the distinctive characters of a few allied plants, and some miscellaneous matter. "The plants selected are well-known and easily-procured types of the fifteen natural orders included in the Syllabus of the First Stage of Elementary Botany issued by the Science and Art Department, as it is believed that no better selection of natural orders, intended as introductory to the study of classification, could possibly be made." As far as can be judged without working through it, the book is well done, and will be a valuable aid to the teacher if honestly used. Mr. Bettany's plan of teaching the art of describing is soundest. His book can hardly be abused, while with Mr. Houston's there is the risk that incompetent teachers may make their pupils simply learn a large part of it by heart, on the chance of one or more of the plants being set in an examination. Occasionally, where the author abandons the sure ground of personal study, he makes slips. Thus more than half the short list of exotic genera of orchids has the names misspelled. The distribution in time and space of the several orders illustrated is given, though somewhat meagrely. Perhaps in the present state of palæophytology the former is not very important. Under *Orchidaceæ*, for example, the Distribution in Time is given as "not represented," which, apart from the fact that it is a contradiction in terms, means nothing more than that fossils referable to this group of plants have not been found, and are perhaps not likely to be. It may be asked, too, what is the value of the evidence upon which the liliaceous genus *Yucca* is dated back to the Trias?

Von den Umwälzungen im Weltall. Von Rudolf Falb (Vienna, Pesth, and Leipzig: Hartleben, 1881.)

THIS work is divided into three parts, with separate headings: (1) In den Regionen der Sterne; (2) Im Reiche der Wolken; (3) In den Tiefen der Erde. The author, whose name has frequently been mentioned in our columns, has lectured in various German cities on volcanic and cosmological phenomena, and eventually went to South America in order to study the great volcanoes of the Cordilleras. He conceived an earthquake theory, and his South American friends induced him to publish it. The result is the book now before us, which was published in Spanish at Valparaiso as far back as 1877 ("Estudio sobre los templores de tierra fundado en la historia del universo"). After a sojourn in South America extending over three years, Herr Falb returned to Europe, and his earthquake theory was frequently mentioned in the press in connection with the Agram earthquakes. The theory is simple enough in itself, and the author has at least the credit of being most enthusiastic in its support and in adducing as many facts in proving the same as can possibly be found. Whether he succeeds in proving it is another question. According to Herr Falb's view, all earthquakes, or at least by far the larger majority of earthquakes, are of a volcanic origin; or, to express it concisely, "earthquakes are subterraneous eruptions." The basis of this theory is naturally the supposition that the whole interior of the earth is an ocean of incandescent matter. This is affected by the attraction of sun and moon in exactly the same manner as the sea and atmosphere are acted upon. The second division of the book therefore represents sun and moon as the generators of storms and tides; and in the third division, the principal one, we see the cause of earthquakes traced to the influence of sun and moon. There is no doubt that the author has a special gift of representing his subject clearly and popularly; his eloquence keeps the reader interested from the first line to the last. He quotes no less than thirty facts, from which he draws thirteen different inferences in proof of the volcanic nature of earthquakes. We regret that space does not permit us to enter further into details, but we can heartily recommend the book to our readers.

The Quantitative Estimation of Phosphoric Acid. By M. H. Joulie. Translated by J. Barker Smith. (Dulwich: Published by the Author, 1881.)

THE laudation of M. George Ville, with which the translator opens his preface, discouraged us at first from further perusal of this pamphlet on the citro-uranic method of determining phosphoric acid in manures; and when we did peruse these sixty pages, our chief impression was derived from the comical literality with which French idioms had been rendered into English words. But after all a good many useful hints may be gathered by practical analysts from this little book. Of course most agricultural chemists are familiar with the difficulties which beset the fair sampling and preparation of manures for analysis, and they are also acquainted with many special contrivances for overcoming these difficulties. But information as to new and improved methods of operating, and as to modifications of old processes, is always acceptable.

The essence of M. Joulie's method consists in the precipitation of the phosphoric acid in a prepared solution of a manure by means of a solution containing citrates of ammonium and magnesium. The precipitate which forms is thus produced in the presence of the lime as well as of the iron and alumina of the original liquid: we should like further proof that the whole of the phosphoric acid is invariably precipitated under the conditions described by M. Joulie, especially as he directs the solutions, if rich, to be kept no more than two hours before the ammonio-magnesian phosphate is filtered off. The second and final stage in M. Joulie's method is the solution of the precipitated phosphate and its titration by a standard solution of uranium nitrate.

The second part of this pamphlet describes the treatment of manurial phosphates with solutions of ammonium oxalate and ammonium citrate in order to determine their "relative assimilability." We are not aware that M. Joulie was the first to employ these reagents in the analysis of phosphates—his announcement of the use of the oxalate being in 1872, and of the citrate during the next year. Anyhow, we must demur to some of the conclusions which M. Joulie draws from his experiments, nor can we accept as satisfactory the final directions for the "assay of superphosphates" with which the last fifteen pages of his manual are occupied. The determination of the phosphoric acid and phosphate dissolved by distilled, or, if you will, carbonated water, from a superphosphate cannot be safely replaced by a determination of the phosphates soluble in ammonium citrate. For we lack proof that retrograded phosphates are equal in value with monocalcic phosphate, which alone possesses an initial diffusive power when it is introduced into the soil.

The Butterflies of Europe. Illustrated and described by Henry Charles Lang, M.D., F.L.S. Part I. (L. Reeve and Co., 1881.)

WE have received Part I. of this work, the approaching publication of which was announced in these columns a few weeks back. The whole of the species (and some prominent varieties, &c.) inhabiting Europe proper will occupy about twenty monthly parts, each containing sixteen pages of text and four coloured plates. The plates

are chromolithographed from the author's own drawings, which appear to be exceedingly well done. We defer a more extended notice until more parts shall have appeared, especially because the subjects illustrated in the first part are almost the least difficult for the chromolithographic process. The text is clearly printed, but a little more care in writing the short descriptions should be exercised. Thus at the very commencement we read as one of the characters of the family *Papilionidæ*, "Larva cylindrical, not spiny, furnished with two retractile tentacles on the second segment." We doubt if this is correct for *all* the European species of *Papilio;* it certainly is not so if exotic species of the same genus are considered; and almost immediately afterwards the author, in defining the genus *Thais* (one of the *Papilionidæ*), says, "Larvæ armed with spines." Nowhere do we find any reference to the veining of the wings, which certainly should have formed part of the sketch of the principal groups given in the Introduction. The author will do well to consider the importance of this suggestion. We presume the chief object of the work is to enable collectors of European butterflies to name their captures, and especially by means of the figures. For this purpose it promises to be exceedingly well adapted.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Chemical Equivalents

MR. J. P. O'REILLY's paper in your last number (p. 274) appears to involve a complete misconception of the theory of chemical equivalents. The equivalents are mere ratios, and are not altered by multiplying their representative numbers throughout by any factor, whether π or any other.

In fact we may write the equivalents of hydrogen, carbon, and oxygen as x, $12x$, and $16x$, without troubling ourselves about the value of x. This is not only the theoretical view, but the one actually used in practice. So far, there is nothing new or special about writing, as Mr. O'Reilly does, $x = \frac{1}{3}\pi$.

But then Mr. O'Reilly goes wrong, and gets results which contradict his hypothesis. When he writes $H = \frac{1}{3}\pi$, and $O = 5\pi$, the real inference is that the equivalents of H and O are as 1 : 15, instead of as 1 : 16 which he started from.

If his π-values are to be taken as corresponding with the equivalents, this simply means that the latter are not to be depended upon within a limit of error of 5 per cent. I think the mistake is not in this respect, but in overlooking the circumstance that the chemical equivalents are not absolute values, but ratios.

Slow Lightning

HAVING just seen the statement of Prof. Tait (NATURE, vol. xxii. p. 341) quoted, as a final authority, against the possibility of distinguishing the source from the termination of a lightning flash, I wish to record a storm that I saw. On May 19 there had been a brisk, hot south-west wind blowing at Gizeh, off the Libyan Desert, at about or over 100° F.; at near sunset a north wind began to come up against it, and there was heavy thunder and lightning all along the line of the mingling of the winds, extending as far as I could see to east and west, and passing a few miles to the north of the Pyramids: the lightning was solely between the clouds, at a height of about one and a half miles; the air around me was 94°, though almost dark. I sat on a rock in front of the door of my tomb (from which I could see eighteen miles over the Delta) and quietly watched the lightning. To my sight there were distinctly differences in the duration of the flashes: some appearing instantaneous and others in which I could see a spot of light occupying an appreciable interval to travel from one cloud to another; and I should be puzzled to draw a hard and fast line between the classes. Does this moving spot-lightning merge insensibly into the variation, of which I saw a fine case years ago near Guildford, where a spark would slowly sail down in the air and then move over the ground before it disappeared?

In any case can these slow flashes (lasting perhaps half a second), seen as well as instantaneous flashes, be disposed of by that blessed word *subjectivity*, which is so comforting to theorists on many objects? Or may not the confession of our ignorance of the cause of ball-lightning be extended to slow flashes in general, instead of treating them just as meteorites were put out of court a century ago? W. M. FLINDERS PETRIE

Bromley, Kent

[Several instances are recorded by Faraday, Joule, and others of flashes which seemed to last for a sensible time. But they are easily explained by one or other of two *veræ causæ*, viz. (1) oscillatory discharges along the same path, succeeding one another at smaller intervals than one-seventh of a second; or (2) phosphorescent matter in the track of the flash. More definite particulars would be necessary before one could decide which was active in the present case.—ED.]

Thought-Reading

As having a bearing upon the hypothesis that in "thought-reading" the information is transmitted by unconscious muscular exertion, allow me to state a modified form of the experiment I tried in the presence of two or three others with Mr. J. R. Brown, who, a few years ago, attracted considerable attention in various parts of the United States by doing precisely what is related of Mr. Bishop in your issue of June 23 (p. 171). After witnessing experiments of the same kind as those stated by Mr. Romanes and performed under the same conditions, I thought to vary them by using a flexible copper wire as a connecting medium. Selecting one, two or three yards long, I held one end in my hand, while Mr. Brown, winding the other end once or twice around his fingers, held it against his forehead, the wire being all the time kept slack between us. Here evidently there could have been no indications received through muscular movements. Yet in this way Mr. Brown would find things concealed or go to certain points determined upon, though apparently with not quite the same readiness and confidence as when the subject's hand was placed against his forehead. Once he partially failed, selecting, instead of a particular spot on the wall I had fixed my mind upon, a small object near it. The experiment in this form was tried with another as his subject, and with equal, if not better, success. GEO. B. MERRIMAN

Rutger's College, New Jersey, July 11

Optical Phenomena

THE photographic halo phenomena described in NATURE, vol. xxiv. p. 260, seem analogous to some observed by me, and upon which, in the spring, I read a paper (since published in the *Notices*, vol. xli. No. 6) before the Royal Astronomical Society. In this I described that not only the sun's disk and the moon's full and partial phases, but also apertures (of similar shape to these) in the shutter of a dark room, when photographed, were, one and all, surrounded by a strong ring halo not visible to the eye. A correspondent essayed some time since to prove in your journal that this halo only surrounded the moon when at full, but on trial the question proved one of time of exposure; and it now seems pretty clear that whatever may be its form and nature, a very bright object when photographed (especially in relief against a dark ground) is found, if sufficient exposure be given, surrounded on the plate by a halo separated from the object by a dark space. Mr. Cowper Ranyard and others attribute these halos to reflection from the back of the plate, a point on which I have not experimented. The dark spot mentioned in connection with the aperture in the rock is probably a reversal of the brightest light owing to the length of exposure.

In two seconds, with Wratten and Wainwright's instantaneous plates, I have found the sun's image so reversed in a camera landscape, showing as a white spot on the negative and a black dot when printed. J. RAND CAPRON

Guildown, July 23

Symbolic Logic

MR. MCCOLL still expresses surprise at my declining to answer a Yes or No question which he was pleased to put to me in

NATURE (vol. xxiv. p. 124). It was, I should think, almost unique in a scientific journal. It turned upon a contradiction which he had detected between a statement which I never made and the fact that he surely entertained an impression that he had somewhere or other (he did not say where) seen me quoted as holding an opinion at variance with that statement. I did not think that time would be well employed in answering it. Even now he talks of his "quotation or misquotation"; a convenient but unusual latitude of expression for a serious case of the latter of these alternatives. Really I am not in the examination-room, and will not therefore attempt to compress into a few paragraphs the answers I should give upon intricate philosophical points, even were the questions reasonably framed. Moreover I must remind Mr. McColl that he does not profess to write as an impartial inquirer or critic, but asked for the insertion of his letter upon the ground that he conceived himself to have been attacked. I have fully explained the only point upon which he had any claim to call for an answer, and therefore now close the correspondence. J. VENN

Achensee, Tirol

Jupiter

THE great red spot on the planet seems unchanged as I saw it on July 8, while the north temperate zone belt (Gledhill's No. 2) shows a development nearly as striking as the equatorial belts.

Millbrook, Tuam, July 20 J. BIRMINGHAM

New Red Variable

THIS star, which I found on May 22 only 9 magnitude (see NATURE, vol. xxiv. p. 164), progressively increased up to 8 m. on June 6, and is now again no more than 9. Its deep crimson colour is unchanged. It is 2° 51′·7 north of α Cygni, and forms, with three other stars, the southern end of a little inverted and irregular cross. It will probably decrease to complete disappearance, at least from telescopes of moderate power.

Millbrook, Tuam, July 20 J. BIRMINGHAM

A Fireball

ON Wednesday the 20th ult., about midnight, a house at Mont Dore, in the Auvergne, was destroyed by a fireball during a severe thunderstorm. My brother, who has lately arrived from thence, did not see the ball himself, but his valet, an intelligent Italian, saw it distinctly. He describes it as a globe of fire about half a metre in diameter, which approached the house obliquely, seeming to pass over a distance of 200 metres in about half a minute. It entered the door of the house and there burst. My brother heard the explosion as well as his valet, and describes it as a dull thud like that of a smothered blast. The house, which was a wooden one, was set on fire, a child burnt to death, and another inmate seriously, if not mortally, injured. Several inhabitants of Mont Dore are said by the valet to have seen the ball, one of whom lived in the adjacent house.

It will be interesting to readers of NATURE to compare the accounts given by Prof. Tait in NATURE, vol. xxii. p. 409.

19, The Boltons, S.W. JOHN TENNANT

Meteor

ON July 23, at 7.15 p.m. (Irish railway time) a meteor passed, travelling nearly from south to north, being lost in a bank of black cloud. It must have been of considerable brilliancy, as it was quite distinct, although at the time the sun was well above the horizon. July 22 from ten to fourteen brilliant red pencils and thin columns of auroric lights were rising at intervals. There were also auroric lights on July 23 between 11 and 12, but much less brilliant. G. H. KINAHAN

Ovoca, July 24

THE COMET

WE have received the following further communications on this subject:—

The following "Preliminary Note on the Photographic Spectrum of Comet *b* 1881," has been communicated to the Royal Society by Dr. Huggins, F.R.S. (For Dr. Huggins's first note on this subject, see NATURE of June 30.)

ON the evening of June 24, I directed the reflector furnished with the spectroscopic and photographic arrangements described in my paper "On the Photographic Spectra of Stars" (*Phil. Trans.*, 1880, p. 669) to the head of the comet, so that the nucleus should be upon one half of the slit. After one hour's exposure the open half of the slit was closed, the shutter withdrawn from the other half, and the instrument then directed to Arcturus for fifteen minutes.

After development, the plate presented a very distinct spectrum of the comet, together with the spectrum of the star, which I have already described in the paper referred to above.

The spectrum of the comet consists of a pair of bright lines in the ultra-violet region, and a continuous spectrum which can be traced from about F to some distance beyond H.

The bright lines, a little distance beyond H, with an approximate wave-length from 3870 to 3890, appear to belong to the spectrum of carbon (in some form, possibly in combination with hydrogen), which I observed in the spectra of the telescopic comets of 1866 and 1868.

In the continuous spectrum shown in the photograph, the dark lines of Fraunhofer can be seen.

This photographic evidence supports the results of my previous observations in the visible spectra of some telescopic comets. Part of the light from comets is reflected solar light, and another part is light of their own. The spectrum of this light shows the presence in the comet of carbon, possibly in combination with hydrogen.

On the next night, June 25, a second photograph was obtained with an exposure of an hour and a half. This photograph, notwithstanding the longer exposure, is fainter, but shows distinctly the two bright lines and the continuous spectrum, which is too faint to allow the Fraunhofer lines to be seen.

Postscript, July 9, 1881.—I have since measured the photographs of the comet's spectrum, and I find for the two strong bright lines the wave-lengths 3883 and 3870. The less refrangible line is much stronger, and a faint luminosity can be traced from it to a little beyond the second line 3870. There can be, therefore, no doubt that these lines represent the brightest end of the ultra-violet group which appears under certain circumstances in the spectra of the compounds of carbon. Professors Liveing and Dewar have found for the strong line at the beginning of this group the wave-length 3882·7, and for the second line 3870·5.

I am also able to see upon the continuous solar spectrum, a distinct impression of the group of lines between G and *h*, which is usually associated with the group described above. My measures for the less refrangible end of this group give a wave-length of 4230, which agrees as well as can be expected with Professors Liveing and Dewar's measure 4220.

In their paper "On the Spectra of the Compounds of Carbon" (*Proc.* Roy. Soc., vol. xxx. p. 494), Professors Liveing and Dewar show that these two groups indicate the presence of cyanogen, and are not to be seen in the absence of nitrogen. If this be the case, the photograph gives undoubted evidence of the presence of nitrogen in the comet, in addition to the carbon and hydrogen shown to be there by the bright groups in the visible part of the spectrum. On this hypothesis we must further suppose a high temperature in the comet unless the cyanogen is present ready formed.

I should state that Mr. Lockyer regards the two groups in the photograph, and the groups in the visible spectrum, to be due to the vapour of carbon at different heat-levels (*Proc.* Roy. Soc., vol. xxx. p. 461).

It is of importance to mention the strong intensity in the photograph of the lines 3883 and 3870, as compared with the continuous spectrum, and the faint bright group beginning at 4230. At this part of the spectrum, there-

fore, the light emitted by the cometary matter exceeded by many times the reflected solar light. I reserve for the present the theoretical suggestions which arise from the new information which the photographs have given us.

THE second evening of its appearing I examined the head of this comet with a McClean spectroscope (with slit) and also with a Hilger's half-prism instrument (a half-size model of the Greenwich one).

The appearances were mainly those seen by other observers, viz., a bright continuous spectrum from the nucleus and a much fainter one crossed by bright lines from the coma. There were however two points of interest which struck me, as I see by NATURE, vol. xxiv. p. 261, they did M. Thollon in Paris. These were : (*a*) The continuous spectrum from the nucleus had a mottled or striated look, but I could not be certain whether dark lines or bright lines or spaces predominated in causing this effect; (*b*) the presence of shorter and additional lines to the three carbon ones, extending beyond the continuous spectrum.

These appearances, I admit, I only recognised indistinctly and with doubt at the time, but, corroborated as they now seem to be, I do not question that there was some ground for them. With reference to the nucleus spectrum it could only have comprised a small portion of solar light as shown by the few Fraunhofer lines detected by Dr. Huggins and others in it. The residue of the bright stripe has been attributed (because continuous) to some incandescent solid or liquid substance; but is this necessarily the case? Is it not possible that the matter yielding this spectrum is still in a truly gaseous form, and do not the appearances above described rather point to the character of a gas spectrum passing from the line or band condition to the continuous one, under its existing circumstances of ignition, pressure, &c. (whatever these may be)?—an effect not without parallel, I fancy, at least in the case of hydrogen. J. RAND CAPRON

Guildown, July 23

A COMET is now visible here. I saw it last Thursday, June 30, at 3·10 a.m. It was in the west, and appeared to me about 30° from the pole star, and 20° above the horizon. The tail was straight and directed towards the pole star. A local paper says this comet was seen to the east at 8 p.m. the preceding day, and that the tail was 20° in length—it appeared to me only 5°.

I regret I cannot send fuller information, but probably the comet is to be better seen in England.

Karáchi, July 2 F. C. CONSTABLE

SEA-SHORE ALLUVION

IT is somewhat remarkable at the present day to find even professional men, when dealing with works of coast defence, attributing the movement of littoral shingle to the tidal currents.

The late Mr. Palmer, C.E., in a well-known paper read before the Royal Society nearly half a century back, Col. Reid, R.E., in an essay published in the commencement of the series of quarterly papers by officers in the corps of Royal Engineers, Mr. Redman, M.Inst.C.E., in a paper on the South Coast of England, read before that society some thirty years back, and another on the East Coast of England seventeen years back, as well as in very numerous reports made by him for a Government department (the War Office) during the last quarter of a century, have all shown that these shingle formations are in no way affected by the tide, which must exercise only a negative influence, the flood and ebb setting in contrary and opposite directions, equal in duration, and neutralising each other. Shingle moles are in effect resultant on the wind waves alone, and are deposited in two parallel ridges or hummocks locally termed "*fulls*," marking the relative range of neap and spring tides, the crest of the last being normally (except in some exceptional cases such as the *Chesil*) ten feet above high water of spring tides with a broad, gently sloping foreshore of sand down to low water; an abnormal tide, resultant on exceptional gales occurring at rare intervals, sometimes breaches the crest and produces great mischief, as at Seaford on the Sussex coast a few years back, which was inundated by the sea, and where the authorities are about to carry out artificial works of defence.

The prevailing movement in the English Channel is to the eastward, or up Channel, due to the fact that south-west winds prevail for nine months in the year; and along the East Coast the movement is southward, due to the particular trend of the coast and the North Sea offing. It really hardly appears necessary to insist on these well-known facts to any one practically acquainted with the subject, or to hydraulic engineers conversant with the surrounding physical conditions of our tidal harbours, estuaries, and rivers.

Notwithstanding this, strangely enough we find a contemporary journal, the *Engineer*, in a series of articles on the Brighton, Hove, and Shoreham beaches, professedly written for the education of public opinion on the subject, themselves ignoring the fundamental laws governing the motion of this marine alluvion, and attributing it to tidal currents instead of to the wind waves, and yet insisting at the same time that the question, as doubtless it is, is an imperial one, demanding the attention of the Legislature.

Thus, October 3, 1879, "Brighton Beach" (*The Engineer*):—

"A very strong *tidal current* sets up the Channel to the eastward, and sweeps with it the rolling shingle"! (*sic.*)

"So rapidly did this disappear under the influence of this *current* that it became necessary to stay its travel by the erection of heavy timber groynes."

"Knowing what we do also of the effect of *sea currents*, it is in our opinion exceedingly questionable *if their carrying powers* can be arrested by anything short of a check which shall produce almost dead water."

One of the last papers read at the Institution of Civil Engineers, on "Upland and Tidal Scour," also attributes the movement of the Norfolk and Essex beaches to the tidal currents.

Nor are local authorities, highway boards, vestries, district boards, and large landowners any more at one than these would-be educators of public opinion on the subject, for we find farmers as a rule sending down their teams and waggons to the sea-shore during winter slack time to collect boulders and pebbles from the sea moles of Nature's forming; railway companies where allowed, and a convenient communication effected, removing it wholesale for ballast of the iron road; lords of the manor conveying it equally wholesale to shipping craft for ballast, until stopped by the strong arm of the law brought to bear on the question by some Government department.

Local magistrates are equally offenders, as recently, about twelve months back, the magistrates sitting at Canterbury authorised their surveyor, after long discussion, as the order was given with the fear of an impending injunction hanging, "Damocles" like, over their heads, to quarry shingle from the sea-shore at Herne Bay for the repairs of the highways; thus robbing the supply travelling up the estuary of the Thames to the westward (the general movement of the belt of shingle being diverted up such estuaries as those of the Thames, Wash, &c.), the material being at the same time so much wanted along the Blue Town frontage at Sheerness, where grave fears have long prevailed, due to the insufficiency of the sea-shore works of defence. This Canterbury decision, taken in the month of January in last year, appeared to us at the time the extreme of rashness, when the interests to

leeward of the proposed road quarry at Herne Bay were considered. The Trinity Corporation would be affected in reference to the defences of the Reculvers—the two spires of the ancient church having been maintained by them for many years as sea marks with stone slopes and groynes for the protection of the cliff. From the fact of their being to the eastward of Herne Bay they may be said to be to windward of the site, still the hastening of the recession at Herne Bay, which has from natural causes alone increased in a marked degree of late, would tend to increase the projection and consequent exposure at the Reculvers.

Next we have the entire landowning interest of the Isle of Sheppy affected by this Canterbury decision, for its northern seaboard retreats at a rapid rate, evidenced by the recent removal of Warden Church, which had been left on the extreme verge of the cliff, due to the extensive slips in the London clay to the westward, which must of course be aggravated if the natural barrier formed by the sea at the base of the cliff is weakened by cutting off the supply coming from the eastward, tending always in its normal state to travel onwards to increase Garrison Point at Sheerness at the outfall of the Medway.

Lastly we have the whole Mile Town and Sheerness frontages affected, where the Government have erected from time to time sea-walls and groynes for the collection of this very beach that the Canterbury magistrates covet for the repairs of their roads. Nor is Sheerness alone affected, but the Queenborough district also, as was evidenced in the great tide of February, 1791, when the whole of the marsh forming the north-west promontory of the Isle of Sheppy was under water, and great loss and damage sustained.

Canvey Island, on the opposite Essex shore, suffered in a similar manner at the same time.

For some years past this practice of removing littoral gravel has been stopped on the Kentish southern coast since Mr. Redman reported for the War Office on the condition of the beaches at Sandown, Deal, Walmer, Dover, Eastbourne, &c., who strongly urged the suicidal nature of the practice, since which the Government and local authorities have had notice-boards planted along the beach imperatively forbidding the removal of shingle.

This general *leeward* movement of shore detritus, due to the prevailing wind waves, has been of late years so clearly demonstrated by the authorities cited, and accepted generally by marine engineers, that it appears strange to find editorial articles for months in a magazine of wide circulation dealing with engineering science which resuscitate the old and exploded theories on the question which are to be found in early geological works, and these articles, if not accepted, have at least remained hitherto apparently unchallenged.

We would sum up this perhaps somewhat lengthy review of a topic, of no mean importance however, having reference to our insular position, by saying that the passage of the heavier particles (the shingle) of a marine mound or natural mole is due universally to the action of the waves, although attributed by many early geological writers to the ocean currents—and its influence on the tidal harbours of our shores, is very important.

The masses of shingle are heaped up coincident in direction with the waves which sort the material in regular gradation; an alternate renewal and withdrawal, due to change of wind, produces a resultant leeward motion due to the wind the particular coast is most exposed to, and the largest pebbles in all these marine alluvion are universally accumulated on the summit, and to leeward of the prevailing winds, due to their greater momentum and to their being less influenced by the recoil wave, compared with sand and the smaller stones.

At the last meeting of the South-Eastern Railway Company we find the chairman (Sir E. W. Watkin, M.P.) stating in reference to the proposed Lydd Railway and the line to Dungeness, that it not only would secure in the future the shortest route to the Continent, but that it also gave them access to an important bed of shingle, from the sale of which they anticipated great benefit! and that they saw their way to *do a large trade* in its conveyance. It was important for road-making, railway-ballasting, and concrete foundations and walls.

This is the not over scrupulous view of the chairman of a leading railway company of one of the most important natural breakwaters on the south-eastern coast, and the uses to which it may be applied as a quarry for the benefit of his company.

The great land-slip which left Warden Church on the verge of the cliff, causing its ultimate recent removal, occurred in September, 1859, and this had been preceded by a similar great fall to the westward about the year 1856, that of 1859 being in effect a prolongation or extension of the earlier one towards the eastern end of the island. The falls are the result of a gradual subsidence occupying some hours, due to the thorough saturation of the London clay by land drainage down several small chines, and the effect of atmosphere and weather on the face of the cliffs and their degradation at the base by the sea during spring-tides. In effect a broad belt of land moves seaward (not a mere abrasion or undermining of the cliff alone), settles vertically downwards, or spreads out, and slides seawards, presenting a new cliff landward at the last parallel fissure, the moving mass attaining a state of rest in the shape of an under-cliff, with a series of parallel terraces rising and falling in the valley of the fall, with the turf and vegetation undisturbed; and the foreshore and shingle are ploughed up by the fall, forming a kind of "moraine" at the base. After a fall the ordinary waste goes on at an average rate of one yard per annum. Some of the trees near the church had settled down bodily on the prisms of earth to which they were attached, some fifty feet lower in level than when they were *in situ*, showing how gradual and vertical had been the subsidence.

The question arises, To what extent are the cliffs in the Tertiary formations saturated or affected by percolation through fissures from the sea, and how far this may be the first cause? There are no appearances of land springs from the cliff face. The whole appears to have squeezed down into a saturated or partly fluid base. The rapid degradation of the Sheppy cliffs was pointed out in an article in the *St. James's Gazette* of May 23, and the absence of any attempts to arrest it. But this constan loss has been eloquently described by Lyell in his great work, "The Principles of Geology," affording as it does a constant supply to the fluctuating foreshores of the River Thames carried up by the superior power of the flood compared with its ebb tide, and brought down again by the prolonged duration of the ebb, aided by upland waters in steps downwards.

SCIENCE AT ETON

ALTHOUGH Eton still ranks as a purely classical school, and has not established a modern side as her rival Harrow has done, yet the study of science is pursued within her walls to an extent which—in some respects at least—is unequalled at any other school. The numbers of the school vary somewhat on each side of 900 boys, about 120 of whom, constituting the Fourth Form, do no science. About seventy boys more from the Fifth Form make up the Army Class, and do no Science unless they take in Physical Geography and Geology for their final examination. But in the Remove and in the greater part of the Fifth Form, which constitutes the chief mass of the school, two lessons a week in science enter into the regular work of each division.

At the present time the Head-Master has twenty-two Classical Assistants, and the Lower Master two. There are nine Mathematical Masters, and four for science, two

of whom also give a little help in the mathematical, and one in the literary teaching. On emerging from the Fourth Form a boy spends a year in Remove, during which his two weekly science lessons are devoted to Physical Geography (*Erdkunde*). Passing on into the Lower Division of the Fifth Form, he is taught the elements of Mechanics, treated experimentally; and during the next year, spent in "Middle Division," he is occupied with Heat, including the principles of the steam-engine. Except in the case of the Army Class, therefore, science is compulsory during three years of every boy's school life. When he enters the Upper Division of the Fifth Form he may drop science altogether, and devote the two lessons a week to additional mathematics. If he does not do this he has his choice between Chemistry, Geology, Physical Geography, and Biology. Many boys leave the school without reaching any higher stage than this; but those who pass on into the "First Hundred" can either give up science in favour of mathematics or of some literary subject, or, on the other hand, they may take up a second scientific subject, and get an additional two lessons a week. During the present School-time they can select from Chemistry (Metals), Physics (Light), Geology (Elementary and Advanced), Physiography, Botany, and Physiology (Muscle and Nerve). Hence a boy who enters Remove at thirteen and stays at Eton until he is nineteen, has the opportunity of acquiring a considerable amount of elementary scientific knowledge. He hears two lectures a week and writes out an abstract of them which is looked over and corrected. His progress is tested by written examinations, the frequency of which depends upon the master he is "up to." Oral

VIEW OF SOUTH FRONT

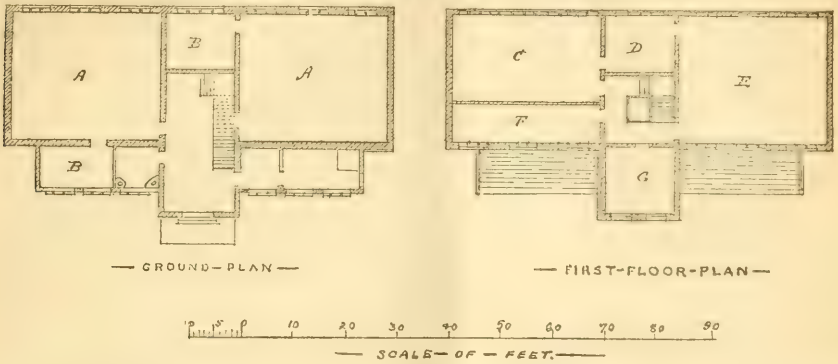
examination is rarely possible except in the upper parts of the school, owing to the necessarily large size of the classes.

At the examinations for promotion which occur every Half, though they are annual as regards individual boys, science is allotted from one-tenth to one-twelfth of the total marks. Although it is not a "pluck subject" like mathematics, yet many a boy who has failed by a few marks in his "general total" regrets not having paid more attention to his science lectures, which would have enabled him to make up the deficit; and the effect is often visible in the improvement in his abstracts during the next School-time.

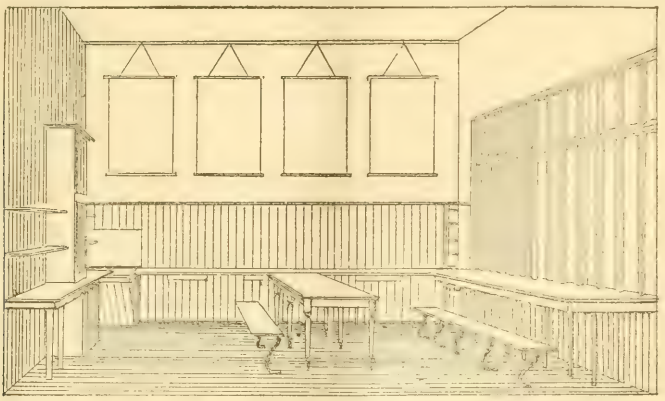
Besides the compulsory science, which is a part of the regular school-work, many boys devote three or four hours of their spare time every week to some form of practical scientific work. Most of them are preparing themselves to try for the prizes given annually by the Governing Body for Chemistry and Physics, Geology and Physical Geography, and Biology respectively. A chemical laboratory, with accommodation for twenty-eight boys at once, has been in use for some years. It owes its existence in great part to the liberality of the present Head-Master, Dr. Hornby, some of the Assistant Masters, and some old Etonians. The laboratory and chemical lecture-room, together with a private laboratory, apparatus-room, store-rooms, &c., form a handsome building in Keate's Lane. Opposite to it is the Round School, formerly used for mathematical teaching, and now converted into a museum. It contains a fine collection of British birds made by the late Provost of King's College, Cambridge, Dr. Thackeray, and presented by him to the school. Some of the specimens are valuable, owing to their being mentioned by Yarrell. There is also a good collection of Lepidoptera made by a former pupil of the school, and presented by his parents after his untimely

death, within two years of his leaving Eton. A tolerably complete series of recent shells has been obtained, and a collection of the more important zoological types is in process of formation. Geology is represented by a fair series of British rocks and fossils, and by remains of the mammoth, hippopotamus, reindeer, and *Bos primigenius*, from the river gravels of the neighbourhood, together with flint implements and neolithic axe-heads which have been dredged out of the river. There are also a few cases of specimens illustrative of volcanic and glacial action, and of the more important processes of Metallurgy, pottery, &c.

Beyond the laboratory, and separated from it by the racquet-courts, are the new Science Schools, which are



being used this Half for the first time, three out of the four Science Masters having been hitherto accommodated in some discarded mathematical schoolrooms. On the ground floor there are two schoolrooms (A, A), each accommodating forty boys, and two preparation-rooms (B, B) opening into them, besides furnace-room, lavatory, &c. On the first floor are the biological laboratory (C), preparation-room (D), and schoolroom (E), all *en suite*, together with a general apparatus-room (F) and stores room (G). The laboratory, which is 28 feet by 16 feet, has accommodation for seventeen boys at once, the table, running along the length of the room, so that the workers shall face the window. Except for the necessary supports, this is continuous along almost the whole of one side of



GENERAL VIEW OF BIOLOGICAL LABORATORY

the room. The other side is occupied by shelves and a large cupboard, half of which is divided up into compartments, one for each boy. A sink, a bookshelf, and a large slate occupy three of the corners, the door being at the fourth. The rooms are all panelled with stained deal to a height of about 5 feet from the floor, which leaves ample space for diagrams above.

The building has been designed and erected by Mr. E. Aborn of Eton, at the cost of the Governing Body of the College, of which Prof. Huxley became a member rather more than a year ago as the representative of the Royal Society. At the request of his colleagues he provided Mr. Aborn with a statement of what he thought was required for the proper accommodation of the three houseless Science Masters, and the result is the eminently practical but inexpensive building, with which all who

use it, both boys and masters, are alike pleased. The schoolrooms are the best in the College as regards light and accommodation for teachers and taught, and offer a striking contrast to the dark and uncomfortable rooms which were built a few years ago for the Mathematical Masters.

Besides providing a home for the science-teaching, the Governing Body have also placed a grant of money at the disposal of the teachers for the purchase of microscopes, diagrams, maps, &c., so that a boy who is really anxious to learn has plenty of opportunities for so doing. The number is not very large at present, as so many other interests have to be considered, such as the classical work and the games. Those, however, who are really taking up science with a view to University honours, find their tutors less exacting about their classical studies; and that the time spent in the laboratory need not interfere with athletics is shown by the fact that the two boys who last year divided the Governing Body's prize for Biology are both distinguished football players. One of them was a prominent member of the school football eleven during the past winter, and has this year rowed for the fourth time in the Eton crew at Henley Regatta. His numerous official duties as "captain of the boats" during the last two years have not prevented his acquiring sufficient knowledge to gain him an entrance exhibition for Natural Science at Oxford, an honour which has only once before been gained by an Etonian.

In addition to the Chemical and Biological Laboratories Eton possesses a well-organised School of Practical Mechanics, consisting of a drawing-room, smithy, and shops for carpentry and metal-working, the whole being under the superintendence of a specially-qualified instructor. Much work is done here out of school-hours, oars, bookcases, cupboards, lathes, and a small steam-engine being some of the practical results of this institution, which is now completing the second year of its existence.

NOTES

THE death, on Sunday, is announced of Prof. Bruhns, the Director of Leipzig Observatory.

THE greatest activity prevails in the Palais de l'Industrie, preparing for the Exhibition of Electricity, but it is feared that, in spite of all efforts, the day of the formal opening will have to be postponed.

THE Municipal Council of Paris has finally granted to Siemens Brothers the authorisation to place rails in the streets for their electrical railway from the Place de la Concorde to the Exhibition. But no viaduct will be constructed, as formerly contemplated, and the rails will be merely laid flat on the pavement.

MR. MUNDELLA stated in the House of Commons the other day that Mr. Samuelson, M.P. for Banbury, and Mr. Slagg, M.P. for Manchester, had consented to investigate the whole question of technical education on the Continent at their own expense. Mr. Mundella was in communication with two other gentlemen, who, he hoped, would join the two mentioned.

A PUBLIC meeting will be held on August 8 at the Society of Arts for the purpose of re-organising the Trades Guild of Learning on a larger basis. Among the supporters of the movement is Sir John Lubbock.

A MEETING was held on Tuesday afternoon at Grosvenor House, Park Lane, to receive and consider a report from the Smoke Abatement Committee on the subject of an exhibition and trials of improved heating and smoke-preventing appliances, to be opened at South Kensington in October next. There was a numerous attendance. The exhibition in question will be held in the East and West Arcades and in buildings adjoining the Royal Albert Hall; and gold, silver, and bronze medals, together with certificates of merit, will be awarded upon the report of a special committee. It will be opened on October 24 and closed on November 26. Dr. Siemens moved the first resolution, declaring that the present smoky condition of the atmosphere of London injuriously affects the health and happiness of the community, besides destroying public buildings, deteriorating perishable fabrics, and entailing in various ways unnecessary expenditure. The speech of Dr. Siemens was a powerful argument in support of the principles thus enunciated, and was warmly cheered. Sir Henry Thompson, in seconding the motion, pointed out that the admixture of unburnt fuel in the shape of smoke with the atmosphere must of necessity be prejudicial to those who had the misfortune to breathe it. He also showed by illustration how highly desirable it was on all grounds of health that the air should be perfectly free from smoke. Dr. Quain, Mr. Spencer Wells, and Mr. G. J. Romanes supported the proposition, which was carried unanimously. Other resolutions were carried, and it was resolved by the meeting to support the efforts now being made to reduce the evil arising from coal-smoke, and to assist in raising the funds necessary for constructing and carrying out, on a practical scale, the competitive testing of the various appliances to be shown, and for providing suitable prizes, medals, &c.

THE new building of the "Deutsche Seewarte" at Hamburg will be inaugurated on September 14. The Emperor William will be present, and will at the same time open a Marine Exhibition connected with the building.

THE annual meeting of the British Medical Association has been delayed a week beyond its usual time in consequence of the Medical Congress meeting in London. It will extend from the 9th till the 12th of August, and is to be held at Ryde, Isle of Wight. The address on medicine will be delivered by Dr. J. S. Bristowe of St. Thomas's Hospital, that on surgery by Mr. Jonathan Hutchinson of the London Hospital, and that on obstetric medicine by Dr. J. Sinclair Coghill, visiting physician to the National Hospital for Consumption at Ventnor.

THE Harvard Geological Museum has lately received from the Smithsonian Institution a series of the types of the fossil plants described by Prof. Lesquereux in connection with his various Government publications. Prof. Lesquereux is also engaged in identifying a large collection of fossil plants made by Mr. Sternberg for the museum. The collection contains nearly all the species thus far described from the Cretaceous beds of Western Kansas.

AN exhibition and congress in connection with the culture of vines is appointed to take place in Milan in September next. The congress, which will be composed of experts from various countries, will be charged with the duty of inquiring into the subject of the disease which has of late years rendered the wine crop so uncertain. The exhibition will consist mainly of appliances for the application to vegetation of insect-destroying agencies, of machines and instruments for grafting, of photographs, plates, and printed publications relative to the vine disease, specimens of vine parasites, and numerous other objects serving similar purposes.

ACCORDING to the Mineral Statistics of Victoria for 1880 the quantity of gold raised in the Colony for the past year was 529,121 oz. 5 dwt., being upwards of 70,173 oz. more than in 1879. While there has been a decided increase in the quantity raised in alluvial mines, the main increase has been in the quartz mines, which have yielded 529,195 oz. The increase in alluvial mines is partly due to the opening-up of new gold-producing areas, and partly to the operations of the diamond drills recently imported.

AN interesting discovery has been made in one of the limestone quarries of Stromberg (Rhenish Prussia). In a small cave, such as occur frequently in the calcareous rock, the skeleton of a cave-bear was found. To judge from the thickness and length of the bones the animal must have measured at least 2½ or 3 metres in length and 2 metres in height. The teeth, of which sixteen were found, are of enormous size. Discoveries of this kind however are by no means rare in this neighbourhood, nor indeed in limestone caves generally.

AN earthquake shock was felt in Eastern France on the night of July 21-22 at Aix-les-Bains, Lyons, Grenoble, Chalons, and other places. The time of the phenomenon was 2h. 3s. a.m. at Lyons and Chalons, and the direction from north to south. No accident is reported in either of these places. The shock was also felt in Switzerland in a large number of places, at Geneva, Morges, Lausanne at about 2h. 45m. a.m. local time; indeed it is stated to have been the sharpest felt in the district since 1854. Nowhere has any accident been recorded. A terrible storm was raging in these regions on the 21st, a few hours before the earthquake took place. Spontaneous currents have interrupted also the telegraphic communications.

A SPECIAL library has been established by subscription in Paris for secular education. The subscribers have resolved to adopt a scientific creed, and to prescribe the use of fiction in books written for young people.

MR. RICHARD ANDERSON, the author of the well-known work on "Lightning Conductors," will contribute a short series of articles on "Thunderstorms: their History and Mystery," to the *St. James's Magazine*. The first article will appear in August.

M. BRUGSCH, conservator of the Boulak Museum, has returned from Thebes with the contents of twenty sarcophagi recently discovered behind the ancient Palace of Queen Hatason. Amongst some 5000 antiquities which have been obtained the most remarkable are several mummies in a perfect state of preservation, and of considerable historical interest.

THE boring of the Arlberg tunnel is proceeding with great rapidity. The length finished since June, 1880, is 1720 metres, and an average yearly advance of 2160 metres is confidently expected after a while. The average of Mont Cenis and the St. Gothard was only 1112 and 1670 respectively. The St. Gothard tunnel will be completed by the end of September, but the lines of approach are not likely to be ready before next spring.

THE *Weserzeitung* reports that near the village of Rantrum a quantity of silver has been found buried about one foot deep in the ground. It consists of thirty-four small bars, six fragments of antique silver ornaments, and eight coins; the latter bear Arabic inscriptions, and may probably be dirhems of the Abassidic Caliph of Bagdad, who lived in the eighth century of the present era. The small bars were formerly used as money, and were weighed, before coins had any conventional value. Ornaments were frequently used in the same way. All the objects found were in a vase.

THE seventh Annual Exhibition held by the British Bee-keepers' Association was opened at the Horticultural Gardens on Tuesday, and will remain open till Monday next.

A REMARKABLE eruption was recently observed by the passengers of the ss. *Glenelg*, at the northern end of the Bay of Plenty, New Zealand. The water rose suddenly to a height of four feet, and spread over a circle of sixty feet in diameter, throwing up sand, shells, stones, and mud. The steamer was only about twenty yards outside the circle. The water continued boiling for some time.

THE *Italia Centrale*, a paper published at Reggio (Emilia) announces that the most remarkable mud-volcano of the province of Emilia, the Salsa di Querzola, has developed an extraordinary activity for a few days past, and has greatly frightened the neighbouring inhabitants. Loud subterranean noise was heard even in the plains around, incandescent lava was ejected to a height of several metres, and an earthquake was also noticed. Large numbers of tourists and curious inhabitants are proceeding to Regnano to witness the spectacle.

A REMARKABLE natural phenomenon is reported from Cs. Gorbo (Szolnok-Doboka [Comitat, Hungary). On June 27 the Buznau Mountain, situated close to the village of Paptelke, suddenly broke in two. The fissure measures 30 to 40 metres in breadth, 25 to 30 metres in depth, and 400 to 500 metres in length. Some of the houses in Paptelke also show cracks, so that the whole seems to have been the effect of an earthquake. A landslip took place at the same time, and a field with an apple-tree in the middle of it has moved about 10 metres nearer to the village. Great excitement prevails in the neighbourhood.

VARIOUS antique bronze arms and implements, altogether weighing about four or five kilogrammes, have been found by forest labourers at a place called Friedhofstannen, in the district of Cattenbühl, near Oberode (Hanover). They were buried in the ground at a very slight depth. The objects consist of battle-axes, a sickle, a knife for taking off the hides of animals, a bracelet, rings. They are supposed to be of Celtic or Phœnician origin. In the neighbourhood of the spot where they were found there is an ancient earth-mound, dating from a very remote period, and inclosed by a circular pit of some 400 yards in circumference, the so-called ring or "kring." Above it was the Hessian fronter fortress of Friedeweh, below it the Spiegelburg.

THE tenth general meeting of the Saxo-Thuringian Apicultural Society will be held at Quedlinburg on July 31–August 2. An exhibition of living bees in hives, also of implements and products of bee-culture, will take place simultaneously.

WE have already received the Calendar of the Newcastle-on-Tyne College of Physical Science for 1881-82.

AN interesting paper on "Prehistoric Hackney" by Mr. J. E. Greenhill, read before the Hackney Natural History Society, has been printed in a separate form.

FROM the *Proceedings* of the Liverpool Naturalists' Field Club we learn that that society has reached its majority. There is the usual account of excursions and an address by the president, the Rev. H. H. Higgins, on "Animal Defences."

THE additions to the Zoological Society's Gardens during the past week include a Silver Fox (*Canis fulvus*, var. *argentata*) from Nova Scotia, presented by Mr. S. R. Platt; three Hedgehogs (*Erinaceus europæus*), British, presented by Mr. W. Dunn, C.M.Z.S.; two Black-tailed Parrakeets (*Polytelis melanurus*) from New South Wales, presented by Mr. Gerald Arbuthnot; a Green Tree Frog (*Hyla arborea*), European, presented by Mrs. Humphrey; six Black and White Geese (*Anseranas melanoleuca*), seven Australian Wild Ducks (*Anas superciliosa*) from Australia, received in exchange. The following, amongst many other insects, may now be seen in the Insectarium:—Perfect specimens of the Swallow-tailed Butterfly (second brood from small larvæ), Camberwell Beauty, Spurge Elephant and Privet Hawk-moths, Northern Brown Butterfly, Chalk-hill Blue Butterfly and Burnet Moth. There are also fine examples of the imago of the Atlas Moth, and larvæ of this moth larger than any yet grown in England.

OUR ASTRONOMICAL COLUMN

ENCKE'S COMET.—The ephemeris of this comet for its approaching re-appearance was issued from Pulkowa last month; but unfortunately the editor of the *Astronomische*

Nachrichten has not considered it was necessary to reprint it in that journal, where the ephemerides for previous appearances have always found a place.

After the death of Dr. von Asten, the calculations for this comet were taken up by Dr. O. Backlund, who has continued the computation of the perturbations by Venus, the Earth, Mars, Jupiter, and Saturn from 1878 to 1881, taking account also of the effect of the so-called resisting-medium on the mean motion and angle of excentricity. The following are the elements of the comet's orbit :—

Epoch 1881, July 2·0 M.T. at Berlin

Mean anomaly	319 26 48·7	
Longitude of perihelion	158 30 5·5	M.Eq. 1881·0.
,, ascending node ...	334 34 3·1	
Inclination	12 53 0·3	
Angle of excentricity	57 43 30·75	
Mean daily sidereal motion ...	1072″·65852	

From these elements we find—

Semi-axis major ...	2·22005	Perihelion dist. ...	0·34301
Semi axis minor ...	1·18547	Aphelion dist. ...	4·09709
Excentricity	0·8454969	Period	1208·21 days

The track of the comet in the heavens at this appearance is a favourable one for observation in this hemisphere. It will be nearest to the earth on October 11, when it will be distant 0·543 of the earth's mean distance from the sun, and situated in the constellation Leo Minor, in the vicinity of the star Fl 21, and the theoretical intensity of light will attain a maximum on November 9, when the comet situated near 89 Virginis will rise about 2h. 15m. before the sun.

The following ephemeris for the month of August is contracted from the accurate one given by Dr. Backlund, and applies to mean midnight at Berlin :—

	R.A.	Decl.	Log. distance from Sun.	Log. distance from Earth.
	h. m. s.	° ′		
August 1 ...	2 56 22 ...	+26 31·0 ...	0·2701 ...	0·2400
3 ...	3 0 23 ...	27 0·3		
5 ...	3 4 31 ...	27 30·2 ...	0·2592 ...	0·2173
7 ...	3 8 46 ...	28 0·7		
9 ...	3 13 9 ...	28 31·9 ...	0·2478 ...	0·1934
11 ..	3 17 41 ...	29 3·9		
13 ...	3 22 22 ...	29 36·6 ...	0·2359 ...	0·1683
15 ...	3 27 14 ...	30 10·2		
17 ...	3 32 18 ...	30 44·5 ...	0·2233 ...	0·1419
19 ...	3 37 35 ...	31 19·8		
21 ...	3 43 6 ...	31 56·0 ...	0·2101 ...	0·1142
23 ...	3 48 53 ...	32 33·1		
25 ...	3 54 58 ...	33 11·2 ...	0·1962 ...	0·0850
27 ...	4 1 23 ...	33 50·2		
29 ...	4 8 10 ...	34 30·3 ...	0·1814 ...	0·0543
31 ...	4 15 23 ...	+35 11·3		

It remains to be seen whether the comet can be perceived with the larger telescopes of the present day with a less intensity of light than 0·24, which was that at the time of its discovery in August, 1848, with the 15-inch refractor at Harvard College, U.S., and which will correspond to about the day of new moon, August 24.

Comet 1881 *c*.—Elements of this comet have been published in circulars issued from Lord Crawford's Observatory at Dun Echt, from which it appears that it will increase very considerably in brightness. The perihelion passage does not take place until August 21. The comet is rapidly approaching the earth.

BIOLOGICAL NOTES

On some New Lower Green Algæ.—George Klebs publishes some very interesting facts about a number of forms of green Algæ found living within the cell-tissues of some flowering-plants. The painstaking way in which the life-history of these have been worked cannot be too sufficiently admired. For full details the student should refer to the numbers of the *Botanische Zeitung* for April and May, where also will be found excellent coloured illustrations of all the species. In order to call attention to these curious species we give the specific diagnosis in detail :—*Family Protococaceæ. Genus Chlorochytrium.*—Through continued division into two parts each cell becomes resolved into spherical zoospores, which upon leaving the mother-cell conjugate within the gelatinous envelope. The zygozoospores before becoming surrounded with a membrane make their way by means of processes into the intercellular spaces of living plants. During the time favourable for vegetation many generations follow one another in a single year; that nearest to the winter falls into a resting stage. *Chlorochytrium lemnæ.*—This species lives in the widened intercellular spaces of the parenchyma of the *Lemna trisulca :* cells chiefly spherical or elliptical; the part of the growing zygospore which remains in connection with the epidermis becomes a spherical cellulose plug. In the next genus, Endosphæra, through continued division into two, each cell falls into a number of daughter-cells surrounded with a membrane, from which, by further division, the spherical zoospores result; those, taking their origin from the same mother-cell, immediately upon leaving it conjugate; they make their way into living tissues like those of the Chlorochytrium. The formation of zoospores only takes place in the spring; the new generation requires a full year to reach maturity. The species *Endosphæra biennis* lives in the intercellular spaces of the sub-epidermal parenchyma of leaves of *Potamogeton lucens:* its cells are mostly spherical; the part of the germinating zoospore which remains in connection with the epidermis soon dies off. In the genus Phyllobium at the time of maturity, the protoplasm of every cell containing chlorophyll is differentiated into cylindrical or spherical portions, through the changing of some of these into smaller ones, zoospores—both macro and micro are formed—these conjugate. The zygozoospores make their way into the stomates of partly living, partly dead leaves of phanerogams. The development of every cell takes a year. The species *Phyllobium dimorphum* lives in the leaves of *Lysimachia nummularia*, Ajuga, Chlora, &c.; the zygozoospores develop processes which grow into branched green tubes among the vascular bundles belonging to the veins of the leaves. The protoplasm of those zygospores which develop a process forms into either a spherical or longish resting cell, which lasts during the winter, and in the next summer again develops zoospores. According to the surrounding circumstances the processes are well developed or not. They may be quite rudimentary, in which case small tubeless resting cells become formed, which form asexual zoospores. In the genus Scotinosphæra every cell shows at the time of maturity a differentiation of its green protoplasm into cylindrical or spherical bodies; by their conjugating, during which a reddish granular substance is secreted, a single mass is formed, through whose repeated division, during which division the granular substance is gradually again taken up, the zoospores are formed. These are asexual, and make their way into decaying vegetable tissues. Their development lasts a year. *Scotinosphæra paradoxa* lives in the dead or dying tissues of *Lemna trisulca*, and also in species of Hypnum. Its cells are mostly spherical, and the zoospores are spindle-shaped. (*Botanische Zeitung*, May 27, 1881.)

On the Influence of Intermittent Illumination on the Development of Chlorophyll.—Dr. Karl Mikosch and Dr. Adolf Stöhr publish the result of their investigations made in the Physiological Institution of the Vienna University. The results of these they summarise as follows :—If a continuedly-lasting 2·5-minutes illumination of etiolated seedlings of barley or oats is compared with an intermittent illumination in the relation of 1 : 1 lasting five minutes, then one will find that in both cases the light is throughout present an equal time. Now if the chlorophyll-formation takes place at the same time as the illumination, then the working of the continued illumination must exactly correspond at the end of 2·5 minutes with the sum of the single effects of the intermittent illumination. As a matter of fact, however, at the end of the continued illumination there has been either no chlorophyll formed, or at any rate no quantity of it that can be pointed out anywhere. On the other hand, the mass of chlorophyll which is formed during the intermittent illumination is beyond doubt capable of being pointed out with a spectroscope. One must therefore imagine that a certain time elapses between illumination and chlorophyll-formation. From this however it follows :—1. That the chlorophyll-formation is a process of photochemic induction. The first trace of chlorophyll that can be pointed out with a spectroscope appears in seedlings of barley and oats grown in the dark after illumination lasting five minutes; it is a matter of indifference whether it is illuminated the whole time through, or only in the relation of 1 : 1 second. One cannot take for granted that in the one case only the half quantity of chlorophyll is formed when an alcoholic solution even shows the absorption-lines of the chlorophyll spectrum, still this will clearly disappear if the solution is made

half as weak again. Consequently the smallest possible effective light for the formation of chlorophyll is attained by intermittent illumination. During the formation of chlorophyll light is supplied in superabundance by a continued illumination in the same manner as at the heliotropic bendings.

A FRENCH physiologist, M. Gley, has made some delicate experiments on himself with regard to the effects of attention and intellectual work on cerebral circulation. His results confirm those of M. Mosso, and he has added some new observations. He finds that the rhythm of the heart through intellectual work is slightly accelerated; and this increase seems in direct ratio of the intensity of the attention. Thus the pulse was more frequent when the author studied geometry, with which he had little familiarity, than when he studied philosophy, of which he had a good knowledge. While the heart-rhythm is accelerated the carotid artery is dilated during cerebral work, and the carotidian pulse becomes dicrotic. But the radial pulse becomes smaller and less ample. The phenomena of congestion observed in the brain persist a certain time after cerebral activity.

CHEMICAL NOTES

BY the action of methylic iodide, in presence of sodium, on an alcoholic solution of morphine, M. Grimaux has succeeded in producing codeine, identical in properties with the naturally-occurring alkaloid (*Compt. rend.*). If ethylic iodide is employed in place of the methyl salt, a new alkaloid differing in composition from codeine by CH_2, is produced. M. Grimaux proposes to call all the homologous bodies of this series *codeines*, and to distinguish the commonly called codeine as *codomethyline*, the new homologue as *codethyline*, &c.

IN *Gazzetta Chimica Italiana* S. Valente describes a striking lecture experiment illustrative of the fact that chlorine replaces iodine from binary compounds. A jar, 500 c.c. capacity, is filled with dry hydriodic acid gas, and another, 250 c.c. capacity, with dry chlorine, the jars being separated by a glass plate, and the larger being uppermost; on withdrawing the plate decomposition of the hydriodic acid occurs with a flash of rose-coloured flame, and separation of iodine.

SS. BARTOLI AND PAPASOGLI claim to have prepared mellitic and hydromellitic acids by the long-continued electrolysis of water, using carbon electrodes (*Nuovo Cemento*).

S. FUNARO describes two nickeliferous minerals from the Apennines in the *Gazzetta Chim. Ital.*, to one of which he gives the formula $(FeNi)_7S_8$, and to the other the formula $Cu_2R_{10}Sb_4S_{17}$, where R = Cu : Fe : Ni = 3·4 : 4·2 : 2·4.

IN continuing his investigation of the action of hydrogen peroxide on aromatic compounds (NATURE, vol. xxiv. p. 111) Dr. A. R. Leeds shows that in some of these compounds the peroxide acts only as an oxidiser, in other cases it replaces hydrogen by (OH), and sometimes both actions occur together (*Berliner Berichte*).

THE same chemist has repeated (*Amer. Chem. Journ.*) many of these experiments, wherein ozone is said to be produced by the action of heat on metallic and non-metallic oxides; he finds that in every case the supposed ozone reaction, obtained by bringing the evolved oxygen into contact with potassium iodide and starch, is due to traces of impurities, generally to traces of chlorine.

ACCORDING to M. Chappuis (*Bull. Soc. Chim.*) the phosphorescence of phosphorus in oxygen or air is an accompaniment of the combustion of phosphorus vapour by ozone. Phosphorus is not luminous in pure oxygen at 15°, and at the ordinary pressure, introduction of a trace of ozone causes luminosity; those substances which hinder the luminosity of phosphorus, *e.g.* turpentine oil, are substances which destroy ozone. If a little turpentine oil is brought along with phosphorus into a tube containing pure oxygen, and a small quantity of ozone is then passed in, the phosphorus exhibits luminosity for a few moments only; M. Chappuis supposes that this is due to the combustion of phosphorus vapour by the ozone, and that the transiency of the phenomenon is explained by the rapid removal of the ozone by the turpentine oil.

EXPERIMENTS on the action of heat on oxides of manganese, by S. V. Pickering, are detailed in *Chem. News*. According to this chemist some specimens of manganese oxides undergo a slow molecular change when kept. Thus a sample containing, when freshly prepared, 85·149 per cent. MnO_2, 9·356 per cent. MnO, and 5·490 per cent. H_2O, *lost* 1·065 per cent. oxygen when heated to 100°, but after eighty days the same sample *gained* 0·24 per cent. oxygen when heated to 100°, and 1·114 per cent. at 195°.

HERR E. RAMANN concludes from his experiments (*Berliner Berichte*) that the passivity of iron is always caused by the formation of a layer of magnetic oxide (Fe_3O_4) on the surface of the iron. In addition to nitric acid, the following liquids induce passivity in iron, viz. ammoniacal silver nitrate solution, solutions of nitrate of silver, ammonium, aluminium, nickel, cobalt, or iron.

THE same author describes an amalgam of iron, nearly of the composition expressed by the formula Hg_3Fe_2, prepared by the action of sodium-amalgam on finely-divided iron in presence of water. Dry sodium-amalgam has no action on iron.

HERREN V. MERZ AND W. WEITH have investigated the action of heat on various amalgams with the view of determining whether these bodies lose mercury regularly as temperature increases, or whether they exhibit the properties of definite compounds. The results, which are detailed in the *Berliner Berichte*, seem to show that many amalgams, *e.g.* of gold, silver, copper, bismuth, lead, cadmium, &c., although very easily decomposed by heat, nevertheless contain their component elements in definite proportions by weight; such amalgams are probably to be classed as molecular compounds. Amalgams of the alkali metals exhibit the properties of definite compounds in a greater degree than amalgams of the other metals.

IN the *Berichte* Herr V. Meyer publishes a note on the densities of the vapours of the halogens, in which he states that he means to relinquish the further working out of these problems to M. Crafts. He states that he has obtained numbers for the densities of phosphorus and arsenic which stand midway between those required by the formulæ P_4 and As_4, and P_2 and As_2.

VARIOUS papers on new nitrogen derivatives of carbon compounds are published in the same *Berichte*, by Prof. V. Meyer and his students; these papers promise results of much interest. Hitherto "azo-compounds" have only been known in the aromatic series; nitroso-substitution compounds of what is apparently azo-ethane are described by Prof. Meyer, especially $NO-C_2H_4-N_2-C_2H_4-NO$. A new series of organic bases called "*ketines*" is also described. The starting-point of this series is *ketine* or nitrosoacetene, $CH_3-CO-CH_2(NO)$.

HERR STRECKER (*Annalen Phys. Chem.*), from determinations of the velocity of sound in chlorine, bromine, and iodine gases, has obtained the following numbers for the specific heats of the e gases:—

	Chlorine.	Bromine.	Iodine.
At constant pressnre ...	0·115	... 0·05504	... 0·03489
At constant volume ...	0·0S373	... 0·04257	... 0·02697
Ratio of values of the two specific heats ...	1·323	... 1·293	... 1·294

From these results it is concluded that the action and reaction between the atoms in the molecules of these gases is different in kind from that which subsists in other diatomic molecules, *e.g.* oxygen or carbon monoxide.

REMSEN has again investigated the action of finely-divided iron in inducing the formation of cyanide when nitrogen is passed over a hot mixture of carbon, iron, and an alkaline metal; he finds (*American Chem. Journ.*) that freshly reduced iron induces a large formation of cyanide, but that iron after keeping for some time loses this power.

FROM experiments on the decomposition of barium carbonate by ammonium chloride solution, Tommasi (abstract in *Berliner Berichte*) concludes that an aqueous solution of sal-ammoniac contains free ammonia and free hydrochloric acid.

REFERENCE was recently made in these Notes to the experiments of Jones on gaseous boron hydride; Reinitzer describes experiments (*Wien. Akad. Ber.*) which appear to show that when dilute hydrochloric acid acts on potassium boride the solid green-brown amorphous powder which is formed is a boride of hydrogen approximately of the formula $B_{3\cdot32}H$.

CONSIDERABLE doubt has been expressed whether calomel is or is not liable to decomposition in the human system, with production of corrosive sublimate. According to experiments described by P. Hoglan (*Chem. News*) calomel is slowly changed

by the action of water at the temperature of the body with formation of corrosive sublimate; and this change is accelerated by the presence of citric acid, sodium chloride, or sugar.

FROM analyses and examination of the distillation vessels used in zinc furnaces, Herren Schulze and Steiner (*Jahrb. für Mineral.*) have found that these vessels contain well-formed crystals of *zinc-spinell* (or zinc aluminate) along with crystals of tridymite. The authors discuss the bearing of their results on the natural formation of minerals of the spinell group in limestones; they point out that the generally accepted hypothesis that such limestones must have been in a fused state for some time, is not necessary, but that the minerals may have been formed by the action of vapour penetrating the solid hot limestone. The action of gases on a softened rock mass may give rise to molecular changes resulting in the production of various minerals.

PHYSICAL NOTES

A CONTINUOUS registering thermometer for recording the temperature of the body has just been described by its inventor, M. Marey. It consists of a brass tube communicating with a Bourdon manometer, containing oil, and closed. Any change of temperature, by altering the internal pressure, makes the curved manometer tube curl more or less, and to it is fixed an index which registers the movements by inscribing them on a recording cylinder. The thermometric bulb may be at some distance from the inscribing apparatus, being connected by a flexible tube of annealed copper. Two such bulbs may be applied to different parts of the body, even to the interior. It is possible therefore to note the relations between the temperatures of the interior and exterior of the body. If we remember rightly, an analogous but more portable instrument was suggested some time ago by Mr. Donald Macalister, but we are not aware whether his instrument is yet before the public.

PROF. E. LOMMEL describes in *Wied. Ann.* a new polarising apparatus in which two plates of platinocyanide of magnesium, cut perpendicularly to the optic axis, are used as polariser and analyser, just as in the tourmaline pincette. Such a section of this crystal transmits a blue light, which, when the angle of incidence exceeds 2°, is found to be perfectly polarised in the plane of incidence, and it therefore can be used, if tilted to that extent out of perpendicularity to the axis, as a polariser for a pencil of parallel blue rays. One curious point in respect to the behaviour of a thin film thus prepared is the following:—Let ordinary non-polarised light be looked at through the crystal while the latter is normal to the line of sight. A white central spot, perfectly circular in form, and non-polarised, is observed in the middle of a blue field, which is polarised at every point radially. The only other crystals which can be used for polarising pincettes are the tourmaline and herapathite (iodo-sulphate of quinine): the point of difference between these and the platinocyanide of magnesium is that while the two former (which are negative crystals) absorb the ordinary ray, and must therefore be cut parallel to the optic axis, the latter absorbs the extraordinary ray, and must therefore be cut at right-angles to the optic axis.

THE galvanic properties of carbon have been closely examined by Dr. Hanichi Muraoka, a Japanese student at Strassburg. He determined the specific resistance and the change of resistance with increase of temperature of all kinds of hard carbon, including Siberian graphite, gas-retort carbon, the artificial carbons used for electric lighting by several well-known firms, and even the graphitic compound used in Faber's lead-pencils. The specific resistance (at 0° C.) of the last was 952·0, while that of the first was 12·2. The artificially-prepared carbons ranged from 36·86 to 55·15. In all however the resistance *decreased* with a rise of temperature, the coefficient of decrease being greatest for the Siberian graphite, least for a carbon pencil prepared from coke by Heilmann of Mühlhausen. This result entirely confirms the recent researches of Siemens and Beetz. The thermo-electric powers of the various samples of carbon were also determined, with respect to that of graphite; their thermo-electromotive force was in every case + to graphite, and varied from 423 microvolts for the Faber pencil carbon to 9·26 microvolts for the gas-retort carbon (of Parisian manufacture) used for battery plates.

HERR P. VOLKMANN observes that in the determination of the specific gravity of heavy liquids, such as quicksilver, by means of the specific gravity bottle or pyknometer, the change of volume of the vessel caused by the internal pressure may introduce a source of error, especially as the glass vessel may suffer a sub-permanent strain from which its recovery is not immediate. He gives an example of this error in the case of a pyknometer provided with a capillary tube marked in equal divisions. This pyknometer was filled with mercury *while standing in mercury* until the top of the column stood at 68·1 divisions. On taking it out of the mercurial bath the column fell to 65·4, and on dipping it it again rose to 68·5. The necessary precautions to avoid this error having been taken, a redetermination was made of the specific gravity of distilled mercury at 0° C., the density of water at 0° C. being assumed (at Pierre's value) as 0·999881. The new value for the density of mercury comes out as 13·5953 ± ·0001, which is a little less than the lowest of the values given by Regnault.

PROF. S. P. LANGLEY has made the following calculation:—A sunbeam one square centimetere in section is found in the clear sky of the Alleghany Mountains to bring to the earth in one minute enough heat to warm one gramme of water by 1° C. It would therefore, if concentrated upon a film of water 1-500th of a millimetre thick, one millimetre wide, and ten millimetres long, raise it $83\frac{1}{3}°$ in one second, provided all the heat could be maintained. And since the specific heat of platinum is only 0·0032, a strip of platinum of the same dimensions would, on a similar supposition, be warmed *in one second* to 2603° C.—a temperature sufficient to melt it!

THE alteration of the zero of thermometers after undergoing sudden changes of temperature is a well-known phenomenon, as is also the gradual rise in the zero in thermometers during the first few months after they have been made. M. Pernet has lately examined the question whether the distance between the "boiling point" and the "freezing point" of a thermometer is constant at all different stages of secular alteration in volume of the bulbs, and finds that this is so, provided the freezing point be determined immediately *after* the boiling point. On the other hand, if the boiling point be determined and a long interval elapse before the zero is determined, there is considerable error. Suppose a thermometer to be (owing to recent heating or to long rest) in any particular molecular state. In this state its reading will probably be in error: but this amount (so far as due to the above cause) may be ascertained by immediately plunging the thermometer into ice, and observing the error of the zero reading. In order that a thermometer should read rightly at any particular temperature it should be exposed for a considerable time to the temperature for which exact measure is desired, or else for a few minutes to a slightly *higher* temperature.

THE transparency of ebonite to heat rays may be shown by the following pretty and simple experiment. A radiometer is set revolving by the light and heat radiated from an argand gas-flame or the flame of a paraffin lamp. When a thin sheet of ebonite is interposed the rotations continue though with slightly diminished energy. But the thinnest sheet of note-paper interposed suffices to check the revolution of the vanes.

PROF. GRAHAM BELL has sought to prove whether the diaphragms subjected to intermittent radiation in one of the forms of the radiophone did or did not execute mechanical vibrations. The experiment of Mr. W. H. Preece of attaching a Hughes' microphone to the disk had led to negative results. But Prof. Bell has shown that the central region of the disk (on which the rays fall) is set into mechanical vibration; and he has proved the point by employing a modification of the mechanical microphone of Wheatstone. A stiff metallic wire is fixed to the centre of a thin metallic disk mounted at the extremity of a flexible hearing tube. When the end of the wire is pressed against any vibrating body its sounds are heard, and the vibrations at different points of the disk of a radiophone can be successively explored. The vibrations are found to be almost entirely confined to the illuminated area at the centre of the disk. A Hughes' microphone attached to the edges of the disk would therefore not easily give any indications. With this simple apparatus one very curious effect was obtained. An intermitted beam of rays was focussed upon a brass kilogramme weight, and the surface was explored with the point of the metallic microphone. Over all the illuminated area and for a very short distance outside it a feeble but distinct sound was detected, but not over other parts.

MR. EDISON has devised a new meter for voltaic currents even more ingenious than the "Weber-meter" which he proposed a year ago to fix in houses supplied with electric lamps. In the

new instrument two copper plates are suspended in an electrolytic cell containing sulphate of copper in solution, and placed in a branch circuit through which a known fraction of the main current is shunted. The copper plates are hung upon a lever arm so adjusted that when by electrolysis one has grown a certain amount heavier (by deposition of copper) and the other grown an equal amount lighter, the lever tips up and reverses the current through the cell, and at the same time moves a registering dial-apparatus through one tooth. The action goes on again until the tilting lever is again overbalanced, and tipped back, when the current is again reversed, and another registration effected. Each "tip" clearly corresponds to the passing of an exact quantity of electricity through the cell, and the registered indications are therefore proportional to the total consumption. *But will it work?*

HERR ED. DORN has investigated the relation between the absolute diameters of molecules of gases and their dielectric capacity on the lines of a suggestion due to Mossotti, that the properties of dielectrics might be explained by supposing them to consist of non-conducting material, in which innumerable minute particles of conducting matter are imbedded.

EVERYONE knows that the very feeblest currents produce audible sounds in the telephone, which is more sensitive than any galvanometer to feeble currents. M. Pellat lately declared that the heat necessary to warm a kilogramme of water one degree would, if converted properly into the energy of electric currents, suffice to produce in a telephone an audible sound for ten thousand years continuously.

GEOGRAPHICAL NOTES

THE preparations for the International Geographical Congress, to be held in September next at Venice, together with a Geographical Exhibition, are advancing rapidly. The *Bolletino* of the Italian Geographical Society announces in its last number that the saloons for the Exhibition are already distributed among the exhibitors, and that the nations which will occupy the most space will be Italy, France, Germany, Austria and Hungary, Russia, and Switzerland. The saloons allowed for the Exhibition in the royal palace being insufficient, it was agreed immediately to proceed to the construction of provisional buildings. The Italian railway companies have granted a reduction of 30 per cent. on the prices of tickets, and of 50 per cent. on goods for members of the Congress. The Austrian Lloyd and the Navigation Company, "Rubattino e Florio," grant a reduction of 50 per cent. on passengers' fares. As to the questions to be discussed at the Congress, the Commission has already published in the *Bolletino* its reports on most of them. Among the questions are :—On the Present State of Telegraphic Determinations of Longitude, by G. Lorenzoni.—On the Determination of the Temperature of Sea-water at Different Depths ; on the Measurement of Depths ; on the State of the Surveys of Coasts, &c., by G. B. Magnaghi ; on the Extinction of Aboriginal Races, by L. Hugues ; and on the Teaching of Geography in Schools, by L. Schiaparelli. We do not hear of any great activity in the collection of British exhibits for the annexed exhibition of geographical apparatus, &c. In England, indeed, no great interest is felt in these congresses. In Russia, on the contrary, a collection of apparatus has for some time been in preparation. M. Grigorieff is to represent the Russian Government and the Imperial Geographical Society at Venice.

THE Swedish Government has decided to send a scientific expedition to Mossel Bay in the course of next year, for the purpose of collecting meteorological information. The expedition will be directed by Capt. Malmberg, and will have to remain during the summer of 1882 and the winter of 1883, in order to obtain the observations of an entire year. Mossel Bay is situated to the north of Spitzbergen, lat. 79°54, long. 16°15. The locality is well known to the Swedes. Prof. Nordenskjöld stayed there in the winter of 1872–73 with three ships. A Swedish man-of-war will take the expedition to Mossel Bay, under the command of Capt. Palander, who, after having fixed the special meteorological station of Capt. Malmberg, will return to Sweden.

WE find in the last number of the *Bolletino della Società Geografica Italiana* a paper on the journey of the late Signor G. M. Giulietti from Zeila on the Gulf of Aden to Harar. This journey was accomplished in 1879, and the narrative was intended to form part of the complete description of all Signor Giulietti's travels, but after his death M. Guido Cora published this small fragment with a map of the country. We notice also in the same publication a paper by Prof. G. Pennesi on the Italian missionaries who travelled in Lower Guinea during the second half of the seventeenth century ; also accompanied with a small map of the country. The author speaks at some length of the two most interesting journeys of P. Dionigi Carli from Piacenza, and of P. Gio. Antonio Cavazzi from Montecuccolo.

COUNT WALDBURG-ZEIL, the well-known scientific explorer, started from Bremerhafen on board the steamer *Luise* for the River Yenisei on the 22nd of last month. The journey is undertaken solely for scientific purposes, Count Waldburg-Zeil intending to make collections illustrating the fauna of the Siberian coast and the sea in that district.

IN a letter just received from the Gaboon Père Delorme reports the foundation of a mission station on the Ogowé River, which the French are making peculiarly their own. The station is placed at the east end of a large island in the river, called by the natives Ozangé-Nengé, *i.e.* Island of Light, which is conveniently situated for communicating with the tribes on the banks of the Ogowé and the Ngunié, one of its principal affluents. Immediately round the station are the Galois ; next to them, on the right bank of the Ogowé, come the Eningas, while further south, on the left bank, or rather on the banks of a branch of the Ogowé, which goes to form Lake Ajingo, are found the Adyombas. Père Delorme expresses a decided opinion that these three tribes are really one people ; they all speak the same language and have the same laws. All of them are very vain and voluptuous. The Galois despise agriculture, and are a trading people. They go up beyond the rapids of the Ogowé in search of india-rubber, ivory, and ebony. The slaves, or in default of them the women, are left to attend to the cultivation of manioc, banana trees, ground-nuts, and sugar-cane.

THE statement that an instalment of the Geographical Society's large map of Eastern Equatorial Africa will be issued this month is, we learn, unauthorised ; and though, probably owing to the long delay which has already occurred, the propriety of issuing the map in parts has been discussed, the question is still left open. When ready, the map will be published by Mr. Stanford.

THE fourteenth Congress of the Italian Alpine Club will meet at Milan on August 29 to September 2 next. An Alpine exhibition will also be held, and three excursions will be made : the first to Erba in the Brianza and the grotto of Pinto, the second *viâ* Como to Varenna on the Lake of Como, and the third to Etico, coupled with an ascent of Monte Grigna.

THE death is announced of the well-known African traveller Herr J. M. Hildebrandt. He died on May 29 last at Tananarivo (Madagascar).

DR. O. FINSCH, the Polynesian traveller, safely arrived at Sydney from New Britain at the beginning of May. He stayed over eight months in New Britain, and has thence sent forty-five cases containing natural history collections to Berlin *viâ* Hamburg. These collections consist of no less than 12,000 zoological specimens, a large number of anthropological objects, besides a series of ethnographical specimens, surpassing in number and completeness any collections yet made in this field. Dr. Finsch intends staying only a short time at Sydney, and then proceeds to New Zealand in order to become acquainted with real Maoris, for the sake of comparison with the Polynesian and Mikronesian races he has studied so minutely. Afterwards the traveller, in continuation of his Melanesian researches, intends to visit North Australia to see and study the so-called Australian negroes. For the same purpose he will try to stay upon New Guinea for some time, as he considers the minute study of real Papuans of great importance.

NEWS has been received from Commander van Boekhuyzen, the leader of the Dutch North Polar Expedition. He writes from Vardö to say that the *Willem Barents* could not reach Spitzbergen. The ice extended in a compact mass from 68° 30′ N. lat. and 6° W. long. to 73° 30′ N. lat. and 14° E. long., some twelve geographical miles to the north of Vardö. There was ice also some thirty geographical miles south of Bear Island. Commander van Boekhuyzen will make another attempt to get northwards in 72° N. lat., and then return home after a month, as he is convinced that Novaya Zemlya is completely inclosed in a barrier of ice.

LETTERS from Dr. W. Kobelt have just been received by the Rüppell Institution at Frankfort, who are the promoters of the expedition. The letters are dated from Oran. Dr. Kobelt's

travels were much impeded by a revolution among the natives and the prolonged drought. Nevertheless four cases, containing collections of seeds, plants, reptiles, insects, and mollusks, have arrived at Frankfort, and Dr. Kobelt has obtained valuable results concerning the geographical distribution of mollusks. With regard to the revolution among the Arabs it appears that they are of opinion that the fifty years during which the Prophet has permitted the French to hold Algiers are now over. Dr. Kobelt has left for Spain, where he will continue his researches.

We are informed that Mr. J. M. Schuver, the adventurous Dutch traveller, who not long ago started on his formidable journey from Cairo to the Cape, is not at Famaka, on the southern frontier of Fazokl, as has been stated, but has established his head-quarters for the present a considerable distance to the south, and actually in the Galla country. A quantity of stores have lately been sent from London to Fazokl for him by way of Suakim, and it is Mr. Schuver's intention to return to Fazokl for them in November next, before proceeding on his southward journey. In the meantime he has established a dromedary post between his camp in the Galla country and Khartum.

In the July number of *Petermann's Mittheilungen* Lieut. Kreitner describes at considerable length the observation made by him while in company with Count Szechenyi, journeying from Sayang in Yunnan to Bhamo in Burmah; a useful map accompanies the paper. Dr. Junker continues his letters describing his travels in the Niam-Niam country, concluding with some important observations on a visit he paid to some of the Monbuttu tribes. Dr. Radde concludes the narrative of his journey to Talysh, Aderbéjan, and Savulan.

We have received from Perthes of Gotha parts 23 to 26 of the new edition of Stieler's Hand-Atlas. This edition has continued to appear with praiseworthy regularity, and will be completed in other six parts.

Among the papers in No. 20 of the *Bulletin* of the Lyons Geographical Society are the following:—The Economic Unity of the Globe, by Prof. C. Stewart Merritt; the South Pole, by M. E. Chambeyrin; the Slave Coast, by Dr. Chappet; South Africa, a lecture by the Rev. M. Coillaird, the missionary who succeeded Serpa Pinto; Lake Fucino, by M. Math. Desgrands.

The U.S. steamer *Alliance*, in search of the *Jeanette* expedition, arrived at Hammerfest on its way to the Siberian Arctic Seas on the 24th inst.

The Egyptian Geographical Society does not often issue a *Bulletin*, but when it does the number usually contains some good matter, often drawn from the archives of the General Staff, the chief of which is President of the Society. The number just published contains, among other matter, a paper on Cape Guardafui by Col. J. Graves of the Staff, and another on the country between the coast and the lofty plateau of Abyssinia by Gen. Stone Pasha.

Commandant Titre, who was formerly at the head of the Survey Department in Algiers, has lately published a large map of Algeria, which embodies all the most recent topographical information.

SOLAR PHYSICS—THE CHEMISTRY OF THE SUN[1]

We have next to consider another method, which enables us to determine the motions of the solar gases. It has been already noticed that it is easy to see the prominences rushing with extreme velocity upwards in radial lines from the photosphere, and that while they are thus being carried up by some violent motion of ejection from below, they are twisted out of the radial line, now to the right, and now to the left, by what we are justified in describing as winds in the atmosphere of the sun. Those were the mere visual phenomena which were incidentally observable the moment a method was obtained of viewing the forms of prominences as well as the bright lines produced by the vapours of which they were built up, and they afforded us an opportunity of getting an insight into solar meteorology.

It was soon however perfectly clear that there was another method, in some respects a much better method, of doing this work. When we consider how it happens that we get any phenomena visible in our universe at all, we are driven to the conclusion that it depends on the fact that bodies in a state of agitation reflect, so to speak, their own state of agitation on the ether, and that the ether carries those vibrations, those agitations to our eyes. So that if we can assume, as we must assume, that the sun with its gases, consisting of hydrogen, magnesium, &c., was communicating its vibrations to the ether, and the ether was communicating in its turn its vibrations to us, it was obvious we had there an opportunity of testing a view which had been put forward by Doppler a good many years ago, to the effect that the light from a moving light source is not the same in all its qualities as light from a fixed one.

The colours which we see in the spectrum are exactly analogous to the notes which we hear in a piano when we go from one end of the scale to the other. Doppler imagined the equivalent of a piano going away from or coming towards the listener with considerable velocity — a velocity comparable, in fact, to the velocity of sound through the air. It is perfectly clear that under these circumstances we should no longer get true concert pitch, for the reason that the note which gives us a certain tone, because it produces in the air so many waves per second, will change its tone if the source of the note is coming to us. Take, for instance, a tuning-fork giving concert C, and imagine it rapidly coming to us: the waves of sound will be crushed together, we shall have more waves in a second falling on the ear, and we shall get a higher note. If we imagine, on the other hand, the tuning-fork is going away from us, the notes will be paid out at longer intervals, so to speak, and we shall get a lower note. In neither case shall we continue to have concert C. A very familiar instance where we do get this change of pitch due to change of motion, is produced in these days of very rapid railway travelling. Any of us who have been at a country railway station when the express is coming by will know that as the train approaches us the note of its whistle is at one pitch, and as it goes from us after passing it changes and gets lower, according to the velocity of the train. A familiar experimental illustration of this principle is to attach a whistle to the end of a long india-rubber tube. If then a person sounds the whistle by blowing through the open end of the tube, and while still blowing whirls it round rapidly in a vertical plane in which an observer is standing, that observer will note that when the whistle is approaching him in one part of the curve, and the waves are therefore being crushed together, the note will appear higher than when it is receding from him in the opposite part of the curve, where the waves are being, as it were, pulled asunder. Now apply that to the light of the sun. The long notes of light are red, and the short notes are blue, and if we sharpen or shorten any light note in any part of the spectrum we shall give that light a tendency to go towards the blue, and if we lengthen or flatten it we shall give it a tendency to go towards the red, so that, for instance, if a mass of magnesium gas, giving the line or note in the green indicated by "*b*" is approaching us with a velocity comparable to the velocity of light, the line will change its position in the spectrum towards the blue; and if we are careful to note the exact amount of change of refrangibility as it is called, we shall have then an absolute method of determining the rate of motion of that mass of gas. This will help us in more ways than one. Suppose we observe the gas at the limb of the sun, we shall then, if we get any change of refrangibility, be justified in calling it a solar wind, because the motion thus indicated would be very nearly parallel to the surface of the sun; but if on the disk of the sun itself—take a spot, for instance, in the very middle of the disk—we get any change of wave-length such as I have referred to, it is perfectly clear that we shall no longer be dealing with what we can justly call a wind, it will really be an upward or downward current. So that this principle enables us at the limb of the sun to determine the velocity of solar winds, and at the centre of the sun to determine the velocity of those up-rushes or down-rushes, in fact, those convection currents to which Prof. Stokes has already directed attention.

The accompanying drawings (Fig. 16) were made when the sun was in a considerable state of agitation in the year 1872. They give us one of the lines of hydrogen, and indicate, I think, amply this kind of phenomenon. We have in the first figure on a large scale the "F" line of hydrogen, the line in the green at the edge of the sun. The slit—the perfectly straight slit—has been worked round the limb in search of a prominence, and it has found one. But the slit is no longer shown us as a perfectly straight line, it is in fact a very irregular one; and further than this it branches

[1] Lectures in the Course on Solar Physics at South Kensington (see p. 150). Revised from shorthand notes. Continued from p. 274.

at a certain height. The line of hydrogen has really divided into two lines of hydrogen, so that there we get, according to the principle just laid down, an indication of the fact that the hydrogen up to a certain height was very nearly at rest, and that beyond part of it was torn away, the line being deflected towards the blue, indicating that it is approaching us. Now the other Fraunhofer lines in the diagram may be looked upon as so many milestones which enable us to measure by the deflection the number of miles traversed by the gas in one second; for these deflections are nothing more or less than alterations of wave-length, and, thanks to Angström's map, we can measure distances along the spectrum in $\frac{1}{10000000}$ mm., and we know that an alteration of $\frac{1}{10000000}$ mm. in the wave-length of the F line towards the violet means a velocity of thirty-eight miles a second towards the eye; and that a similar alteration towards the red means a similar velocity from the eye; so that carrying the part

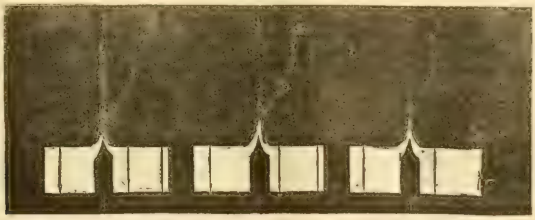


FIG. 16.—Alterations of wave-length in prominences. The dots show $\frac{1}{10000000}$ mm.

of the line which has the greatest deflection from the normal down to the dots, we find that the velocity of the solar wind under observation at that time was something like 114 miles per second.

In the second figure this same prominence is seen a short time afterwards. The tremendous rush of hydrogen has descended somewhat nearer the sun, and bringing that in the same way down to our milestones, we can give that velocity at something like fifty miles per second. The wind velocities measured in this way have amounted to 140 miles a second. The phenomena of convection currents give us velocities which very often amount to forty or sixty miles a second.

This method enables us to determine a matter which a few years ago we could not have determined in any other way. I refer to the fact that the motions of the solar winds are to a very large extent cyclonic. These various effects have been produced by varying the position of the slit a very little indeed over a small prominence.

In the first of the accompanying diagrams it will be seen that the hydrogen line indicates by its change of refrangibility that the gas is receding from us, that the waves are being lengthened out, and that they therefore have approached towards the less refrangible end of the spectrum. In the third diagram we see that in that part of the prominence the rays were being deflected towards the violet; that is to say, they were approaching us. In the middle of the prominence we get indications that they were both receding and approaching, as shown in the second diagram. Now if anybody in the moon had as good a method as this of measuring an earthly cyclone, he would see exactly this sort of thing—the part of the cyclone receding from him would give a deflection in one direction, the centre of the cyclone would give him both deflections, because he would get currents going in both directions, and on the other side of the cyclone he would get a deflection in the other direction.

So obvious and so very definite did these observations at last become that a new word had to be coined to separate the forms of

FIG. 17.—Solar cyclone. Left-hand diagram, retreating side of cyclone on slit; centre diagram, both sides on slit; right-hand diagram, advancing side on slit. The right-hand side of each diagram is the most refrangible.

the prominences as seen with a widened slit from the forms which were assumed by the prominences depending on their rate of motion.

Fig. 18 is a diagram of what have for this reason been called "motion forms," because such forms are really not the forms of the prominences at all—have nothing whatever to do with the shape of the prominences, but are simply produced by the various changes in the refrangibility of the light brought about by the varying motions in different parts. It is a very remarkable fact, noticed at the time, that some prominences seem to be shot up like so many smoke rings—little cyclones. And many of the strangest motion-forms are due to this cause. The velocities in the same prominence vary very much from the time it leaves the photosphere until it arrives at its greatest elevation in the sun's atmosphere, indeed the variations in any one prominence are almost as great as the variations observed between any two prominences.

There is another important fact connected with this: when the phenomena are observed close to the limb it is very often seen that the dark line on the surface of the sun is broken; in fact we got a doubling of the dark "F" line in exactly the same way as we got this doubling of the line in the prominence itself. That taught us that not only were these motions enormous in the case of vapours ejected from the sun, but that the subjacent parts of the sun itself—of the photosphere rather—felt that same influence.

The next point observed was (and this was an observation very difficult indeed to make near the limb) that whenever we got any very considerable velocity we got a new order of phenomena altogether, indicated in these two diagrams (Figs. 19 and 20).

It was found that the absorption of the hydrogen, or of the magnesium, or of the sodium, as the case might be, was enormously reduced; that for that part of the sun there was practically no absorption; but instead of absorption an excessive brilliance

in that part of the spectrum where the dark line would otherwise be. In the brighter portion between the two small spots (Fig. 19) the absorption is replaced by an exceedingly brilliant radiation, so brilliant indeed that it is quite impossible to draw a diagram so as to give any idea of the intense brilliancy of some of these little spots of light which one sees in the spectroscope; they fatigue the eye enormously, although they cover such a very small portion of the field of view.

Accompanying this intense radiation there is a gradual fading away of the absorption line; it wanes, and fades, and becomes almost invisible; while, on the other hand, on the other side or in other places, instead of getting a brilliant patch of light of the same width as the "F" line, we get one many times broader. We have also the absorption deflected to the left, or red end of the spectrum, and on this side it is gradually fined or eased off, so that it is very difficult to determine exactly where this broadened, deflected "F" line actually ceased to give us absorption; whereas at the other side, where it changed its refrangibility towards the blue end of the spectrum, we have an enormous patch of light. Now the explanation of that is perfectly simple: we have at one part of the spot an enormous up-rush, an ejection of hydrogen so intensely hot that it declines naturally to absorb the light from anything behind it, because it finds nothing hotter. This gradually replaces the absorbing hydrogen which was driven down again with considerable velocity, and so changed its refrangibility towards the the red.

Enough has been said already to show that this method of studying solar phenomena *in situ* has really helped us enormously

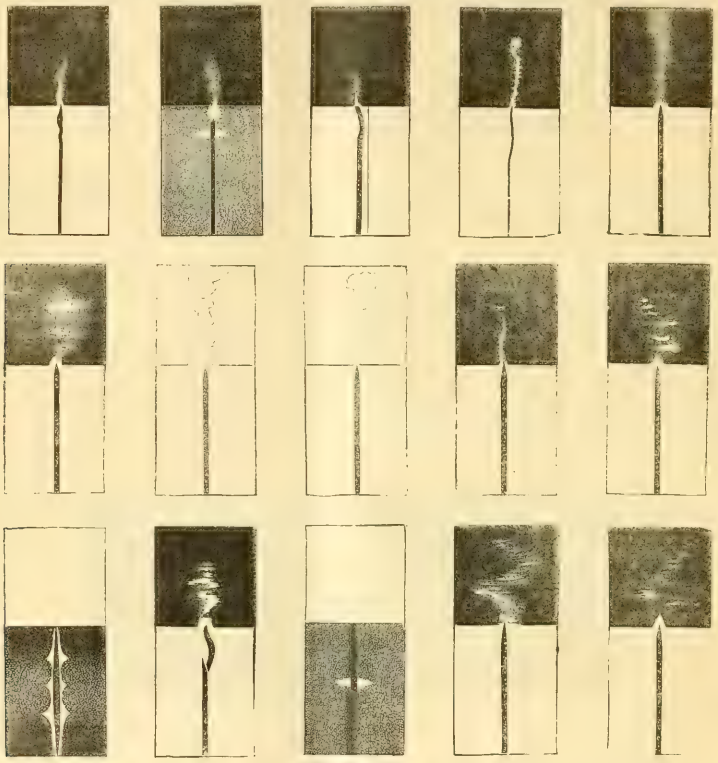

Fig. 18.—Motion-forms.

with regard to the chemical nature of the sun. We can allocate the absorption of the hydrogen, magnesium, and so on; we can see *where* they are absorbing, and in the phenomena just referred to, where they cease to absorb, we get bright lines.

What, then, was the totality of the knowledge which had been acquired a few years ago with regard to the chemical nature of the sun's atmosphere taken as a whole—the sun's atmosphere from the upper reaches of the coronal atmosphere down to the region where, doubtless, the spot phenomena are located?

I have two little glass vessels here which ought to point what I wish to say. I have here hydrogen arranged so that I can make it luminous with a minimum of agitation. If we examined it with the spectroscope, we should find it would give the F line alone, there is nothing red about it. Now there is a region around the sun which gives us something very like that in colour, and something absolutely like it, so far as the result of spectroscopic observation is concerned. Now we have in this other little tube hydrogen in a condition to be considerably agitated, because instead of allowing it to occupy a globe, it is arranged so that the electric current has to pass through a fine capillary space in which the gas is inclosed. That is a condition which is supposed to give us the effect of high temperature. This really does give us something like what we see in the next lower solar region. This is exactly the same gas as we have in the globe, but it is treated differently, and the effect is widely different. As we pass from few encounters of molecules to many it is very much more luminous, and it is red. The level which gives such a spectrum as is got from the capillary tube is considerably lower than the one which gives us the F line alone (Fig. 21).

Is this all? By no means; going further down, as was pointed out at an early stage of the work, we get some lines seen in the spectrum of magnesium all round the sun at certain periods of the solar activity. Underneath this again we get a layer in which lines seen in the case of sodium are almost as constantly seen. Still a lower depth—practically there is no end of them—in which we get the lines of iron and other substances. There are many lower variable layers depending upon local disturbance. Tacchini, an eminent Italian observer, has studied these very carefully. We have by these observations a means of determining the fact that the solar atmosphere consists of what may be very conveniently and justly called a very considerable number of layers; and what happens with these layers is this. If the sun is quiet, or if we observe any particular part of the sun at any particular time at which it is not agitated, the layers

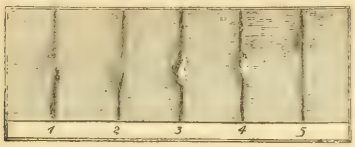

FIG. 19.—Contortions of F line on disk. 1 and 2, rapid downrush and increasing temperature; 3 and 4, uprush of bright hydrogen and downrush of cool hydrogen; 5, local downrushes associated with hydrogen at rest.

visible at that time, few in number, are nearly concentric (Fig. 21), but the moment there is any agitation in any part of the sun the lower layer shoots up into the next layer above it; the next shoots up into the one next above that; and so on (Fig. 22). How far into the very confines of the solar atmosphere this sort of action goes we do not know, because it wants more time to observe than is afforded by an eclipse, but it is certainly known that from the very lowest layer to the upper hydrogen one the layers are made to obey this same sort of rhythmic movement, and extend over like so many shells, so many domes on every part of the sun, which is being most violently agitated at the time.

So far then we have so many shells, so to speak, so many thinnings out.

Tacchini's work shows well that observers have gone into considerable detail. I give one of his drawings (Fig. 23).

The figure shows two separate portions of the chromosphere, and below each portion is shown the height above the photosphere

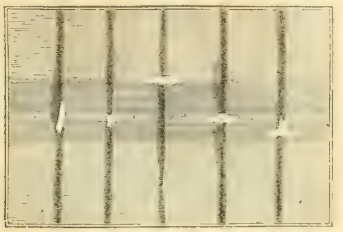

FIG. 20.—Contortions of F line on disk, in connection with spots and uprushes of bright hydrogen.

to which the various substances indicated by the lines given extend. Thus it will be seen that the magnesium stratum reaches the greatest elevation, next the so-called 1474 stuff, then an undetermined substance giving a line at wave-length 4923, another giving a line at 5017, then sodium, then a substance giving a line between B and C, another with a line between B and A, and finally one with a line at 5369. The two last layers were not observed in the second portion shown. It will be observed that most of the lines seen in these small prominences belong to substances with which we are totally unacquainted on this earth.

So much for the first results obtained in localising the solar chemistry. We pass from a general theory, saying that the absorption is above the sun, and that the sun consists of such and such chemical substances; we go to a very much more complete picture, in which we say that the solar absorption is built up by vapours of so and so, and so and so, corresponding to different heights, changing their forms, changing their shapes, changing their quantities at different times, some of them being more particularly visible in the bright ejections from the interior called prominences, and others again being brought to our ken in those down-currents called spots.

Attention must next be drawn to another method of observation, or rather to the same method extended to a different line of work.

Kirchhoff, when he examined the sun as a whole, compared it with the light of a light source as a whole. So far we

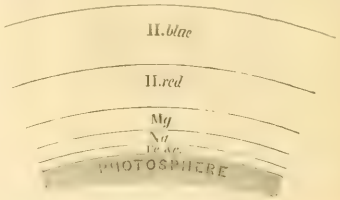

FIG. 21.—Stratification of the solar atmosphere.

have seen the difference in the results obtained when we pass from the question of observing the sun as a whole to that other more detailed question of observing every little bit of the sun that we can get at.

Now is it worth while to do this with the light source?—that is the question. Take the case of the volatilisation of iron in an electric arc. It is obvious that light from every part of a light source placed in front of a slit must enter every part of it; and if there are any differences between the light proceeding from the upper pole or the lower pole, or from the globule of iron which is being melted, and exists in a liquid form, or from the vapours of iron which surround that liquid globule—if there are any differences in these, those differences must be absolutely lost, for the reason that light from all these parts of

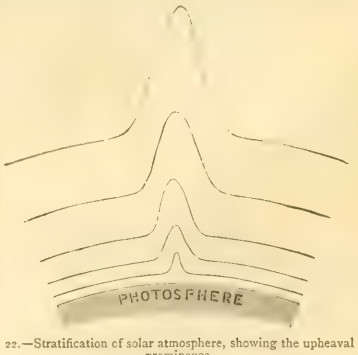

FIG. 22.—Stratification of solar atmosphere, showing the upheaval of a prominence.

the very compound phenomenon we are observing will pass to every part of the slit. But if we introduce a lens between the light source and the slit of the spectroscope, if as we throw an image of the sun on the slit, so we throw an image of the light source on the slit, we ought really to bring about a very considerable difference. For instance, we ought to be able to focus the light on the slit in such a way, that if there are any differences we should see them. It is difficult for us on a small scale to see whether there are any such differences, but if in an electric lamp we so volatilise a piece of iron, and throw the image on a screen, we readily see that there are very considerable optical differences in the various parts of the image of the light

source. We have the upper and lower pole, the globule of iron volatilising, and the vapour, both in the arc, properly so-called, and the accompanying flame. It is obvious that if we throw the image of the arc on the slit we can examine the vapour without getting any light from the pole. It is also obvious that if we arrange the slit horizontally while the current is passing in a vertical direction from one pole to the other, we shall be able,

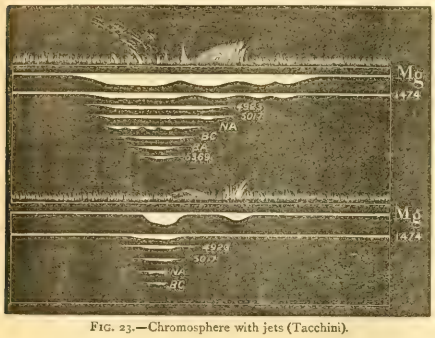

FIG. 23.—Chromosphere with jets (Tacchini).

by moving the slit upwards, to see if there are any differences observable in the vapour, first in the region where we have intense boiling and volatilisation going on, and in the necessarily cooler region where the arc is in contact with the outer air. Photographs taken in this manner show what is really observed in the case of iron under these circumstances. Whether we use the artifice of a horizontal arc with a vertical slit, or a vertical arc with a horizontal slit, does not matter, provided we keep the slit immersed in the light of the arc, and thus reflect the light from the poles, and at the same time arrange the slit so that we can compare the light in the interior portion of the light source with the light nearer its boundaries—if we take all these precautions we shall then get in the case of every substance such a result as here exhibited (Fig. 25). We have in the centre a complete spectrum, its intensity being gradually toned down, and some of the lines being left behind as we look up and down towards the boundary where we have the spectrum of that portion of the arc which was the last to retain its luminosity in consequence of its cooling. If we take horizons from the central portion of the diagram to the point furthest distant from that central axis, we find at last the light becomes absolutely monochromatic. The iron vapour at this distance from the central axis really was only radiating to us the vibration rendered visible to us by that one line. As we get nearer and nearer the centre of agitation the spectrum becomes more complex, until at length when very near the central axis we get a great many short lines introduced,

FIG. 24.—Arrangement for obtaining long and short lines. Image of the horizontal arc on slit plate of spectroscope.

so that the spectrum at that point is most complex. This I am anxious to draw attention to with some insistence, because we shall understand at once the terms long and short lines from this diagram, and about those long and short lines there will be a great deal in the sequel.

The figure shows the much more simple spectrum of sodium.

In all cases under the conditions mentioned it is quite easy to obtain photographs of longs and shorts; the longest line in the middle is D, that to the left the line is the green, and we find that one line excels all the others, and reaches a greater distance from the central axis of the photograph.

An electric lamp can be arranged to show the long and short lines of sodium on a screen; the arrangement is rather a delicate one, but the point is that we have not, as in the case of the other electric lamps, vertical poles, but horizontal ones, and we have a vertical slit close to the horizontal poles in the very middle of the lamp, so that if the experiment is carried far enough we can then prove the accuracy of the statement that the line is an image of the slit, because the slit generally melts, and we see the shape of the lines varying on the screen as the melting goes on. The lines are of different lengths: the yellow is longer than the green, the green longer than the red, and so on.

Results obtained by this method have a very important bearing upon every question connected with solar spectroscopy. When these spectra were observed—the spectra of the longs and shorts, of course we had a perfectly new set of phenomena to deal with. In all preceding spectra all the lines had been practically shown of the same length, or else the lengths had represented their intensities. But here we had, in the case of each chemical substance, to deal with the remarkable fact that when that chemical substance was examined in this way, some of the lines were long and some of them were short, and the question naturally arose,

FIG. 25.—Spectrum of sodium, showing the long and short lines.

how is it that some of the lines are long and some of them short? That question was an exceedingly difficult one to answer: I do not know that it has been thoroughly answered yet; but while researches were being made for the answer to this question certain general statements became possible which are of very considerable importance to us in our inquiry. Such a general statement as this, for instance, that if we take, say, some iron, observe its spectrum, and then mix some manganese with it, and observe the spectrum of the mixture: if the quantity of manganese is very small, we shall only get the longest line of manganese; if the quantity of manganese is increased, the next longest line will come in; and so on. So that if the spectrum of any specimen of iron was photographed, it was at once easy to see whether there was an impurity of manganese in that iron. If you make the admission that the spectra of iron and manganese, and so on, were the spectra of bodies not decomposable at the temperature which you were employing—if, for instance, there was a great quantity of manganese existing as impurity in the iron—you got a great many lines, and of course with the quantity of admixture the number of lines would go on increasing until you had 50 per cent. of each, when you would have the greatest number of lines of iron and the greatest number of lines of manganese you could ever get together, but in no case then would you get *all* the lines of iron, or *all* the lines of manganese.

The great importance of this result was, that it enabled any spectroscopist, or any chemist who chose to take the trouble and devote the time to it, to examine as to the existence of impurities in different substances: not to determine the absolute amount of impurity, but enabling him to say that in specimen A

there is a greater impurity of X than there is in specimen B, or there is a greater impurity in specimen Y of article A than there is in specimen Z, and so on. The statements were not absolute, but they were relative, and being relative they were certainly a very great advance on anything which had been done before, because until this question of longs and shorts was introduced it was almost impossible to see how to eliminate impurities.

There was another matter: it was easy to determine the behaviour of compound bodies under the action of heat by such a method. For instance, if we took the salts of calcium, or of strontium, salts which have as perfect and as complete spectra of their own as iron itself—if we heated them properly, that is to say, if we did not employ too high a temperature, and did not give them a chance of oxidising, it was exceedingly easy to see how these would behave when the heat was gradually increased, and it was then found that the longest line of the metal was always the one which showed itself first. In fact the metal always behaved as an impurity, and brought out this longest line first, in exactly the way that the smallest quantity of impurity would do. Those are small examples of the work which was done, in the one case by working at a constant temperature, and in the other case by working at varying temperatures; and you see it was possible in this way to prepare maps in which all the various impurities of one substance in another may be eliminated. A diagram will explain the way in which this new knowledge could be utilised. We have, for instance, a great number of photographs of iron, cerium, vanadium, and a great number of other chemical elements. We have compared the spectrum of each of the chemical elements with all the others, compared the lines of iron with cerium, titanium, and so on. The question now is, Given these photographs bristling with impurities—for if there were no impurities present in these photographs we should not know that our photograph was a good one—how are we to produce a map which shall be absolutely purified, in which none of these impurities shall have any effect? This diagram (Fig. 26) will show the process which was rendered possible by this long and short series of observations. We have three spectra, with their long and short lines. We have compared A with B, and we find that in the photograph which gives us A compared with B we have so many lines of the two substances. Now we say if B exists in A as an impurity, the longest line of B will be there. We look for the longest line of B, and we find it, and we put a minus sign over that line in A to show it is most probably due to an impurity of B. We then ask if there is any more B in A, and we naturally look for the next longest line of B; we find that, and we put a minus sign over that, and then we look for the next longest line, and mark that; then we look for the next one—it is not there—then there is no more of B in A. In that way, if we knew everything, we should years ago have been able to determine a spectrum of a substance A, from which all traces of the spectroscopic effects due to the presence of a substance B, had been eliminated, and we might go on with substance C, and so on, and in that way eliminate the effects of C as well as B from the substance A.

I am the more anxious to insist on this work because I shall have to show subsequently that it took a very long time to execute it; that the work is of a very rigid nature; and that, so far as I know, no other suggestion has been made with regard to obtaining pure spectra; and of course, if we wish to study the physics of the sun—especially the chemical physics of the sun—the first desideratum, as Kirchhoff saw, and as Angström saw, and as we all see now, is to have a series of maps absolutely and completely beyond all suspicion.

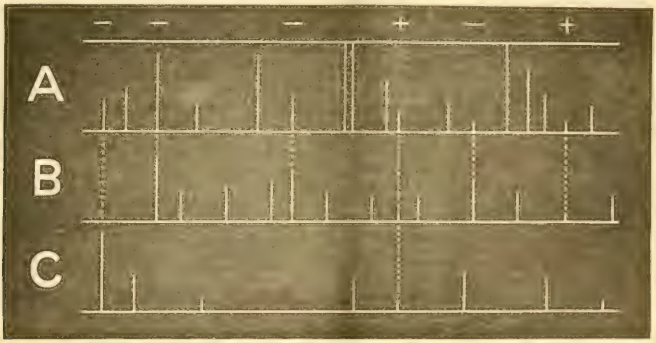

FIG. 26.—Diagram showing the process by which impurities are eliminated from spectra. The lines marked — are due to impurities of one substance in another; those marked + are common or basic lines.

There is one other question to be referred to. Was the way perfectly clear, taking the work as it stood, four or five years ago? Did our chemical theories then explain all the facts which had been gathered by many men in many lands touching this localisation of the solar chemistry? The localisation had depended on using existing maps, whether tainted with impurities or not, observing the lines in all prominences and spots. Was everything, I say, quite clear, let us say, five years ago? I shall have to show that things were by no means at all clear; that any one who took the trouble to bring together all the results which had been obtained up to that time would have found not only that there was a rift in the lute, but that there was a very big one, and that the discord which grew upon one as one went into detail either with regard to the spectrum of the spots or with regard to the spectrum of the prominences, or with regard to the general localisation of the solar layers, was really very much more remarkable than the accord, and that although, of course, an immense deal had been done towards elaborating a view of solar chemistry a great part of which would stand, still there was a great deal which required a considerable amount of attention and a great deal more which suggested that there was still a higher light to be got before we could really face the magnificent problem with which we are attempting to grapple.

J. NORMAN LOCKYER

(*To be continued.*)

ANCHOR ICE

IN an address recently delivered at the Annual Convention of the American Society of Civil Engineers in Montreal, Mr. James B. Francis, the President, gave, *inter alia*, the results of his observations, during forty years, of anchor ice. The following is the passage in question:—

A frequent inconvenience in the use of water-power in cold climates is that peculiar form of ice called anchor or ground ice. It adheres to stones, gravel, wood, and other substances forming the beds of streams, the channels of conduits, and orifices through which water is drawn; sometimes raising the level of watercourses many feet by its accumulation on the bed, and entirely closing small orifices through which water is drawn for industrial purposes. I have been for many years in a position to observe its effects and the conditions under which it is formed.

The essential conditions are, that the temperature of the water is at its freezing-point, and that of the air below that point; the surface of the water must be exposed to the air, and there must be a current in the water.

The ice is formed in small needles on the surface, which

would remain there and form a sheet if the surface were not too much agitated, except for a current or movement in the body of water sufficient to maintain it in a constant state of intermixture. Even when flowing in a regular channel there is a continued interchange of position of the different parts of a stream, the retardation of the bed caused variations in the velocity which produce whirls and eddies and a general instability in the movement of the water in different parts of the section. The result being that the water at the bottom soon finds its way to the surface, and the reverse. I found by experiments on straight canals in earth and masonry that coloured water discharged at the bottom reached the surface at distances varying from ten to thirty times the depth.[1]

In natural watercourses, in which the beds are always more or less irregular, the disturbance would be much greater. The result is that the water at the surface of a running stream does not remain there, and when it leaves the surface it carries with it the needles of ice, the specific gravity of which differs but little from that of the water, which combined with their small size, allows them to be carried by the currents of water in any direction. The converse effect takes place in muddy streams. The mud is apparently held in suspension, but is only prevented from subsiding by the constant intermixture of the different parts of the stream; when the current ceases the mud sinks to the bottom; the earthy particles composing it, being heavier than water, would sink in still water in times inversely proportional to their size and specific gravity. This, I think, is a satisfactory explanation of the manner in which the ice formed at the surface finds its way to the bottom; its adherence to the bottom, I think, is explained by the phenomenon of *regelation* first observed by Faraday; he found that when the wetted surfaces of two pieces of ice were pressed together they froze together, and that this took place under water even when above the freezing point. Prof. James D. Forbes found that the same thing occurred by mere contact without pressure, and that ice would become attached to other substances in a similar manner. Regelation was observed by these philosophers in carefully arranged experiments with prepared surfaces fitting together accurately and kept in contact sufficiently long to allow the freezing together to take place. In nature these favourable conditions would seldom occur in the masses of ice commonly observed; but we must admit, on the evidence of the recorded experiments, that under particular circumstances pieces of ice will freeze together or adhere to other substances in situations where there can be no abstraction of heat.

When a piece of ice of considerable size comes in contact under water with ice or other substance it would usually touch in an area very small in proportion to its mass, and other forces acting upon it and tending to move it would usually exceed the freezing force, and regelation would not take place. In the minute needles formed at the surface of the water the tendency to adhere would be much the same as in larger masses touching at points only, while the external forces acting upon them would be extremely small in proportion, and regelation would often occur, and of the immense number of the needles of ice formed at the surface enough would adhere to produce the effect which we observe and call anchor-ice. The adherence of the ice to the bed of the stream or other objects is always down stream from the place where they are formed; in large streams it is frequently many miles below; a large part of them do not become fixed, but as they come in contact with each other, regelate and form spongy masses, often of considerable size, which drift along with the current and are often troublesome impediments to the use of water-power.

Water-powers supplied directly from ponds or rivers or canals frozen over for a long distance immediately above the places from which the water is drawn, are not usually troubled with anchor-ice, which, as I have stated, requires open water up stream for its formation.

UPON A MODIFICATION OF WHEATSTONE'S MICROPHONE AND ITS APPLICABILITY TO RADIOPHONIC RESEARCHES[2]

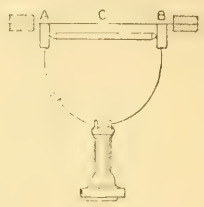
IN August, 1880, I directed attention to the fact that thin disks or diaphragms of various materials become sonorous when exposed to the action of an intermittent beam of sunlight,

[1] Paper clx. in the *Transactions* of the Society, 1878. Vol. vii., pages 109, 168.

[2] A paper read before the Philosophical Society of Washington, D.C., June 11, 1881, by Prof. Alex. Graham Bell.

and I stated my belief that the sounds were due to molecular disturbances produced in the substance composing the diaphragm (Amer. Assoc. for Advancement of Science, August 27, 1880). Shortly afterwards Lord Rayleigh undertook a mathematical investigation of the subject, and came to the conclusion that the audible effects were caused by the bending of the plates under unequal heating (NATURE, vol. xxiii. p. 274). This explanation has recently been called in question by Mr. Preece (Royal Society, March 10, 1881), who has expressed the opinion that although

Fig 1.

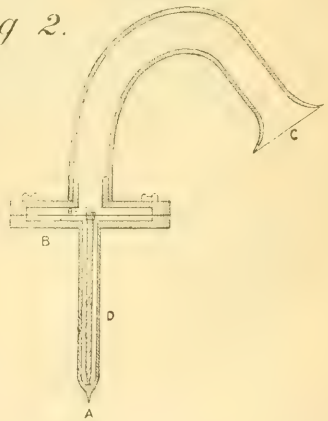


A B, Carbon supports; C, Diaphragm.

vibrations may be produced in the disks by the action of the intermittent beam, such vibrations are not the cause of the sonorous effects observed. According to him the aërial disturbances that produce the sound arise spontaneously in the air itself by sudden expansion due to heat communicated from the diaphragm, every increase of heat giving rise to a fresh pulse of air. Mr. Preece was led to discard the theoretical explanation of Lord Rayleigh on account of the failure of experiments undertaken to test the theory.

He was thus forced—by the supposed insufficiency of the explanation—to seek in some other direction the cause of the

Fig 2.



A, Stiff wire; B, Diaphragm; C, Hearing tube; D, Perforated handle.

phenomenon observed, and as a consequence he adopted the ingenious hypothesis alluded to above. But the experiments which had proved unsuccessful in the hands of Mr. Preece were perfectly successful when repeated in America under better conditions of experiment, and the supposed necessity for another hypothesis at once vanished. I have shown in a recent paper read before the National Academy of Science, April 21, 1881, that audible sounds result from the expansion and contraction of the material exposed to the beam, and that a real to-and-fro

vibration of the diaphragm occurs capable of producing sonorous effects. It has occurred to me that Mr. Preece's failure to detect with a delicate microphone the sonorous vibrations that were so easily observed in our experiments might be explained upon the supposition that he had employed the ordinary form of Hughes' microphone shown in Fig. 1, and that the vibrating area was confined to the central portion of the disk. Under such circumstances it might easily happen that both the supports (A B) of the microphone might touch portions of the diaphragm which were practically at rest. It would of course be interesting to ascertain whether any such localisation of the vibration as that supposed really occurred, and I have great pleasure in showing to you to-night the apparatus by means of which this point has been investigated (see Fig. 2).

The instrument is a modification of the form of microphone devised in 1827 by the late Sir Charles Wheatstone, and it consists essentially of a stiff wire (A), one end of which is rigidly attached to the centre of a metallic diaphragm (B). In Wheatstone's original arrangement the diaphragm was placed directly against the ear, and the free extremity of the wire was rested against some sounding body, like a watch. In the present arrangement the diaphragm is clamped at the circumference like a telephone-diaphragm, and the sounds are conveyed to the ear through a rubber hearing-tube (C). The wire passes through the perforated handle (D), and is exposed only at the extremity. When the point (A) was rested against the centre of a diaphragm upon which was focussed an intermittent beam of sunlight, a clear musical tone was perceived by applying the ear to the hearing-tube (C). The surface of the diaphragm was then explored with the point of the microphone, and sounds were obtained in all parts of the illuminated area and in the corresponding area on the other side of the diaphragm. Outside of this area, on both sides of the diaphragm, the sounds became weaker and weaker, until at a certain distance from the centre they could no longer be perceived.

At the points where one would naturally place the supports of a Hughes microphone (see Fig. 1) no sound was observed. We were also unable to detect any audible effects when the point of the microphone was rested against the support to which the diaphragm was attached. The negative results obtained in Europe by Mr. Preece may therefore be reconciled with the positive results obtained in America by Mr. Painter and myself. A still more curious demonstration of localisation of vibration occurred in the case of a large metallic mass. An intermittent beam of sunlight was focussed upon a brass weight (1 kilogram.) and the surface of the weight was then explored with the microphone shown in Fig. 2. A feeble but distinct sound was heard upon touching the surface within the illuminated area and for a short distance outside, but not in other parts.

In this experiment, as in the case of the thin diaphragm, absolute contact between the point of the microphone and the surface explored was necessary in order to obtain audible effects. Now I do not mean to deny that sound-waves may be originated in the manner suggested by Mr. Preece, but I think that our experiments have demonstrated that the kind of action described by Lord Rayleigh actually occurs, and that it is sufficient to account for the audible effects observed.

EXPERIMENTAL DETERMINATION OF THE VELOCITY OF WHITE AND COLOURED LIGHT[1]

THE method employed in this research to measure the velocity of light resembled the method of M. Fizeau, subsequently employed by M. Cornu. A revolving toothed wheel is employed in the same way to alter the intensity of the light reflected from a distance. In the present method, however, there are two distant reflectors instead of only one. They are separated by a distance of a quarter of a mile. The observing telescope and the two reflectors are almost in the same line. The observer sees two stars of light, which go through their phases with different periods as the toothed wheel is revolved at increasing speeds. One star is increasing, while the other is diminishing, in intensity, with increase of speed of the toothed wheel. The speed required to produce equality of the light is determined by means of a chronograph.

By choosing such a speed as gives a maximum of one star at the same speed as a minimum of the other, a pair of observations eliminates all cause of doubt arising from varying brightness in the stars, and ratio of the width of a tooth to the width of a space. The distances were observed by triangulation with the Ordnance Survey 18-inch theodolite, using as a base line a side of one of the Ordnance Survey triangles. The source of light was an electric lamp. The velocities (uncorrected for rate of clock, and reduction to a vacuum) measured are as follows :—

187,707
188,405
187,676
186,457
185,788
186,495
187,003
186,190
186,830
187,266
188,110
188,079
Mean ... ... 187,167 miles a second.

The correction to vacuum is + 54 miles a second. The correction for rate of clock to a mean solar time is + 52 miles a second.

The final results for the velocity of the light from an electric lamp *in vacuo* is 187,273 miles a second, or 301,382 kilometres a second.

Using Struve's constant of aberration 20·445″, we obtain for the solar parallax the value 8·77″, and for the mean distance of the sun 93,223,000 miles.

On February 11, 1881, the reflected stars were seen to be coloured, one reddish, the other bluish. The particular colour of a particular star depended upon the speed of rotation of the toothed wheel. That star which was increasing with increase of speed of the toothed wheel was reddish, that one that was diminishing with increase of speed was bluish. This seems to be caused by the fact that blue rays travel quicker than red rays.

A number of tests were made to judge of the accuracy of this conclusion, and they confirmed it. In the final arrangements, the electric light was acted upon by a bisulphide of carbon prism, and part of a pure spectrum was used. Differential measurements were then made to find the difference in velocity of rotation of the toothed wheel, required to produce equality of red and of blue lights. The most convenient method was to use a driving weight slightly in excess of that required to produce equality of the light, then to fix to the pulley carrying the weights one end of a piece of stout india-rubber tubing, the other end being fixed to a point above. This gradually diminished the effective driving weight. The equality of red lights was first noted, the colour of the light was changed, and the interval of time until the blue lights were equal was measured. The rate at which the india-rubber diminished the speed was afterwards measured by the aid of the chronograph, and thus the difference of speed determined. The mean of thirty-seven determinations in this and other ways gave the result that the difference in velocity between red and blue lights is about 1·8 per cent. of the whole velocity, blue travelling most rapidly.

The general conclusion seems to be supported by a comparison of the velocity of light measured by M. Cornu and Mr. Michelson, where the source of light usually employed is taken into consideration. These are the only accurate measurements of the velocity of light hitherto published. They give us the following results :—

	Usual Source of Light.	Velocity in kilos. a Second.
Michelson's research ...	The sun near horizon ...	299,940
Cornu's ,, ...	Lime light	300,400
The present ,, ...	Electric light...	301,382

Classifying the sources of light used by Cornu, we get the following approximate relative velocities :—

Source of Light.	No. of Observations.	Approximate Relative Velocity.
Petroleum	20	298,776 kilos.
Sun near horizon ...	77	300,242 ,,
Lime light...	449	300,290 ,,

All these results seem to support the view that the more refrangible the source of light, the greater is the velocity. But the evidence of the present observations, indicating an excess of

[1] Abstract of a paper by Dr. J. Young, F.R.S., and Prof. G. Forbes, read before the Royal Society, March 19.

velocity for blue over red light, seeming to exceed 1 per cent. of the whole, must rest upon the merit of the present observations themselves.

SCIENTIFIC SERIALS

Journal of the Royal Microscopical Society, June, 1881, contains: On the diatoms of the London Clay, by W. H. Shrubsole, with a list of species and remarks by F. Kitton (Plate V. Fig. 1).—On the estimation of aperture in the microscope, by Prof. E. Abbe (woodcuts).—On a new species of Hydrosera (Wallich), by Dr. H. Stolterforth (*H. tricornata*), Plate V. Figs. 2, 3.—Summary of current researches relating to zoology and botany (principally Invertebrata and Cryptogamia), microscopy, &c., including original communications from Fellows and others.—Proceedings of the Society.

The Scottish Naturalist, July, 1881, contains under Phytology—Dr. Stirton, on the genus Usnea and a new genus allied to it.—Rev. J. Stevenson, Mycologia Scotica (continued).—J. Cameron, the Gaelic names of plants (continued).—Dr. F. B. White, preliminary list of the flowering plants and ferns of Perthshire.

PARIS

Academy of Sciences, July 18.—M. Wurtz in the chair.—With regard to a telegram from Gabès about a recent earthquake there, and detonations preceding the shocks, M. Boussingault remembered having heard detonations at intervals during an earthquake in South America in 1827.—Observations of comet *b* 1881 at Paris Observatory, by MM. Tisserand and Bigourdan.—Theory of the plane flexion of solids, &c. (continued), by M. Villarceau.—On the reduction of quadratic forms, by M. Jordan.—Researches on glycolic ether, and on oxides of ethylene, by M. Berthelot.—On the trajectory of cyclones, and on the announcements transmitted by telegraphic cables, by M. Faye. Commandant Bridet has lately shown that if Mauritius and Réunion (Bourbon) were connected by means of a cable, the latter might be informed eighteen or twenty four hours in advance of the arrival and direction of storms. M. Bridet is trying to get this project realised.—On the integration of a linear differential equation of the second order on which evection depends, by M. Gyldén.—Effects produced by sulphide of carbon on vines of Beaujolais, by M. Henneguy.—Ephemerides of the planet (103) Hera for the opposition of 1881, by M. Callandreau.—On the tails of comets, by M. Flammarion. He replies to M. Faye, and supports M. Berthelot's theory of electric illumination.—On the vision of stars through comets, by M. André. The enlargement of the image is probably a simple effect of diffraction indicating the presence of solid or liquid nuclei in the mass of matter.—On a function similar to modular functions, by M. Poincaré.—Distribution of energy in the normal spectrum, by Prof. Langley. He gives two curves obtained from observations with his new instrument for a diffraction spectrum after and before zenithal absorption by our atmosphere. The curve of light coincides almost exactly with that of heat. There is enormous absorption by the atmosphere in the blue.—On a method enabling us to amplify the displacements of the plane of polarisation of light, by M. H. Becquerel. When monochromatic luminous rays, polarised rectilinearly, traverse a half-wave crystalline plate, the emergent rays are polarised rectilinearly in a plane which, relatively to the axis of the plate, is symmetrical with the plane of polarisation of the incident waves. This known property is utilised for the purpose indicated.—On the velocities of propagation of the inflammation in explosive gaseous mixtures, by MM. Mallard and Le Chatelier. In one form of apparatus each end of the tube has a lateral orifice communicating through a caoutchouc tube with a small chamber closed with an elastic membrane, which, being pressed outwards at the moment of explosion, affects an inscribing style. The propagation in the larger tube in not of normal velocity, unless the part not yet inflamed remains as rest during the whole phenomenon. In a tube closed at one end the velocity is much greater if the gas be fired from the closed end. Even in the other case violent movements often occur in the unburnt mass, and there are various irregularities.—On the decomposition and enlargement of bands of the rainbow, by M. Ritter. Near the observer (to a distance of about 1°50m.) the two systems of cones, with parallel axes from the eyes, by which the rainbow is defined, are quite separate; thus if the drops are within that distance one should see two distinct arcs or rings. Illustrations of this deduction and others are given.—On the extraordinary temperature of July, 1881, by M. Renou. The temperature of 37°·8 in the Park of Saint-Maux, on July 15, is undoubtedly the highest ever experienced in Paris or the environs.—On hydrosulphurous acid, by M. Schutzenberger.—Action of sulphur on various metallic solutions by MM. Filhol and Senderens. It decomposes them (in heat), producing more or less complex reactions.—Separation and determination of alumina and oxides of iron and chromium, by M. Carnot.—Industry of magnesia, by M. Schloesing. This is preliminary to an account of new ways of extracting magnesia from the water of salt marshes, and even from sea-water.—On injury done in Greece by anthracnose and *Peronospora viticola*, by M. Gennadius.—On the origin of trunks of fossil trees perpendicular to the strata of the coal formation, by M. Fayol.—On some points relative to anthracic immunity, by M. Toussaint.—On a new malady of domestic geese observed in the Commune of Viviers-les-Montagnes (Tarn), by M. Caravin-Cachin.—Experiments on yellow-fever patients with phenic acid, phenate of ammonia, &c., by M. de Lacaille.—On the Cretaceous system of the Northern Sahara, by M. Rolland.

FOSSIL CRINOIDS

Mémoires de la Société Paléontologique Suisse. Monographie des Crinoïdes Fossiles de la Suisse. Par P. de Loriol. (Genève: Imprimerie Charles Schuchardt, 1877-1879.)

Iconographia Crinoideorum in Stratis Sueciæ Siluricis Fossilium. Auctore N. P. Angelin, Opus postumum edendum curavit Regia Academia Scientiarum Suecica. Cum Tabulis XXIX. (Holmiæ: Samson et Wallin, 1878.)

PROF. P. DE LORIOL of Geneva, who is so well known for his researches on the fossil sea-urchins, has been occupying himself for some time past with the study of the fossil Crinoids. A handsome volume, consisting of 300 pages of text and twenty-one somewhat crowded quarto plates, contains the results of his work on those discovered in the stratified rocks of Switzerland. It originally appeared in three parts, which formed portions of the volumes issued by the Palæontological Society of Switzerland for the years 1877-79.

The total number of species described by Prof. de Loriol amounts to 125, of which thirty-nine are new to science. The series commences with the well-known "Lily-Encrinite" from the Muschelkalk, and ends with a species of D'Orbigny's doubtful genus "*Conocrinus*" from the Nummulitic Eocene of Wesen. Palæozoic Crinoids are, of course, conspicuous by their absence; so that Prof. de Loriol was not hampered by having to deal with any obsolete system of classification. For the primary divisions of the class he adopts Dujardin's modification of Pictet's system. This throws such very diverse forms as *Encrinus*, *Apiocrinus*, and *Pentacrinus* into one family, the *Pycnocrinides*, which is especially characterised by the thickness of the plates of the calyx.

Each of these genera, however, is best regarded as the type of a separate family. In fact, Pictet's "family" of *Pycnocrinides* includes nearly all the non-palæozoic Crinoids or Neocrinoidea except the *Comatulæ*, and is far more comprehensive than an ordinary zoological "family."

Encrinus and *Apiocrinus* are fairly well represented in the Jurassic rocks of Switzerland. Two species of the former genus are described by Prof. de Loriol, one of which is new; and there are four species of *Apiocrinus*, one of which is new, though founded only on the characters of the stem. *Millericrinus* and *Pentacrinus*, however, are considerably more abundant. Thirty-three species of the former are described, two being Liassic and three Cretaceous; while there are no less than forty-three *Pentacrinus* species, six of which are Cretaceous, and one from the Infra-Lias (Rhætic).

Most of the species are necessarily founded only on the characters of isolated joints and fragments of stems, and are therefore only of provisional value; for two or more joints, the markings on which differ considerably, may really belong to different parts of the same stem. Nevertheless, after making allowance for these possibilities, Prof. de Loriol finds a considerable number of different types of stem which are confined to particular horizons. They thus acquire some stratigraphical value, and it is convenient to name them, but the names can only acquire a permanent value (or otherwise) when we are acquainted with the calices associated with the stem-joints in question. This is, unfortunately, but far too rarely possible.

The genus "*Pentacrinus*" is a large one, and it is almost necessary to separate off some of the best marked varieties as distinct generic types, just as has been done with *Apiocrinus*. Prof. de Loriol has attempted this subdivision in two cases, in one of which he seems to us to be fully justified, though we cannot say the same for the other. He attempts to re-establish the genus *Cainocrinus* of Edward Forbes, to include those species of *Pentacrinus* in which the basals form a complete ring and cut off the radials entirely from the top stem-joint. The characters of the stem and of the faces of its component joints are identical with those of the ordinary *Pentacrinus* type; and there is so much variation in the development of the basals among the different *Pentacrinus* species, both recent and fossil, that it is hardly worth while to separate off one of the extreme terms of the series as a distinct genus. Besides the fossil species mentioned by Prof. de Loriol *Cainocrinus* would include the recent *Pentacrinus Müllerí*, Oersted, from the Caribbean Sea, *P. Wyville-Thomsoni* from the North Atlantic, and *P. Maclearanus* of the *Challenger* dredgings.

The genus *Balanocrinus* was established by the late Prof. Louis Agassiz for a crinoidal fragment that he believed to be a calyx with an attached stem-joint; and he described the terminal face of the latter as resembling those of the stem-joints of *Pentacrinus subteres*. Prof. de Loriol, however, finds this fragment to be merely an abnormally swollen piece of stem, with the borings of some parasitic mollusc. But the stem-joints of *P. subteres* have rather different terminal faces from those of the ordinary *Pentacrinus* species; and Prof. de Loriol therefore proposes to retain the name *Balanocrinus* for this and similar forms, in which only the rim of each joint-face is crenulated, and not the central ends of its petaloid divisions as in the ordinary *Pentacrinidæ*. No calyx has ever been found associated with stem-joints of this nature except perhaps that of *P. Fisheri*. This name was given by Edward Forbes to a specimen from the Oxford clay of Weymouth that was described by Baily, who did not, however, say much about the stem-joints. Prof. de Loriol directs the attention of English palæontologists to this subject, in the hope of finding out whether Baily's species is a *Balanocrinus*. If it be so, the original specimen would acquire additional value from its being the only one with the calyx preserved.

The well-known genus *Eugeniacrinus*, which is made the type of a new family by Prof. de Loriol, is represented in the Swiss rocks by nine species, ranging from the "Oxfordien" to the "Néocomien." The curious form *Phyllocrinus* with its deeply incised radials was described by d'Orbigny as a Neocomian Blastoid allied to *Pentremites*; but it has become less interesting since Prof. Zittel showed it to be a near ally of *Eugeniacrinus*. It is represented in Switzerland by nine well-marked species, which range from the Lower Oolites to the Neocomian deposits.

Comatulæ are also abundant in the Swiss rocks, twelve species being described by Prof. de Loriol, eleven of

which are new. These are equally distributed through the Jurassic and Cretaceous series; but there are none as old as our own *Actinometra Cheltonensis* from the Inferior Oolite of Gloucestershire, nor as young as various species from the Margate chalk. One of the Neocomian species belongs to the sub-genus *Ophiocrinus* of Semper, which is characterised by the presence of five undivided rays. There are only three recent species referable to this type, all of them inhabiting different portions of the Pacific Ocean. With the *Comatulæ* must be included two species of the curious genus *Thiollericrinus*, recently mentioned in these columns (vol. xxiii. p. 377) as being a permanent larval form.

Prof. de Loriol's Monograph with its abundant illustrations forms an excellent supplement to the fourth volume of Quenstedt's wonderful "Petrefactenkunde Deutschlands," which deals with the *Encriniden*. Taken together, the two works give us a very complete account of the Mezozoic Crinoids of Central Europe. We understand that Prof. de Loriol is now working out the French Crinoids in the same way as he has treated the Swiss ones, and we hope that he will be enabled to complete this somewhat extensive task with an equally satisfactory result. This will render a similar work on the British Crinoids more than ever necessary, and we trust that it may be accomplished within a reasonable time.

The second book mentioned at the head of this article is the late Prof. Angelin's "Iconographia of the Silurian Crinoids of Sweden." It has been published as a posthumous work by the Swedish Academy, and is unquestionably the finest work on Crinoids that has ever appeared. It consists of twenty-nine beautifully-printed folio plates, which illustrate the marvellous wealth of Crinoids and Cystids in the Silurian rocks of Sweden. Some of the figures, such as those of *Crotalocrinus*, are excessively intricate, and they are all admirably clear and well-arranged. The lamented death of the eminent Swedish palæontologist has unfortunately prevented these figures from being as useful to his successors as they would have been, had he lived to describe them. They have been edited by two of his colleagues, Professors Lovén and Lindström, who have classified the genera and species according to the system which they found sketched out in Prof. Angelin's notes and manuscripts. Unfortunately, however, the classification is an entirely unnatural one, depending upon the number of basal plates in the calyx. Wachsmuth, the chief authority in America on the Palæocrinoids, has already pointed out that while it brings together very distinct types such as *Rhodocrinus* and *Poteriocrinus*, genera which are very intimately related, such as *Platycrinus* and *Dichocrinus*, are widely separated. Among the true Crinoids forty genera are figured, comprising 176 species, many of which are new. They are arranged into twenty-three families, but as these are not defined we are unable to learn the principles upon which they were established.

There are also figures of twenty-three Cystidean species, arranged into nine genera, including one new one, which fall into three sections, the *Apora*, *Gemellipora*, and *Rhombifera*. So far as can be judged from the species referred to each section, Angelin's classification is something more than an introduction of new names for the three divisions of the group which were sketched out by Müller. Neither of the three genera included in the *Apora*, Angelin, are ordinarily referred to the *Aporitidæ*; but *Echinosphærites aurantium* and *Caryocystites*, von Buch, were placed by Müller among the *Rhombiferi* or "Cystideen mit Porenrauten"; while the third genus, *Megacystites*, Hall, is ordinarily referred to the *Diploporitidæ*, which is a parallel group to the *Gemellipora*, Angelin.

As in the case of the true Crinoids, we are unable to learn the principle of Angelin's classification of the Cystidea. It is not likely therefore to be adopted, at any rate for the present. Possibly, however, it may stand the test of future discoveries better than the Müllerian system, though we do not think this contingency a very probable one.

In spite of the inconsistencies which we have mentioned, the "Iconographia" must be indispensable to every student of the Palæocrinoidea. A glance through its pages makes one long to see some really good illustrations of our British species. There are many specimens of the utmost beauty and novelty, both in our public museums and in private collections, which we hope will some day be properly described in a "Monograph of the Fossil Crinoids of the British Isles."

OUR BOOK SHELF

The Countries of the World. By Robert Brown. Vol. vi. (London: Cassell and Co.)

We are surprised that, after so many volumes of this work have been devoted to the description of America and Asia, the whole of Europe and of Africa are disposed of in a single volume, a considerable part of it being devoted, moreover, to the Turkish Empire. This last is allotted 58 pages, whilst the whole of Europe is dealt with in 104 pages, and the whole of Africa in other 104 pages. Moreover, why should Turkey have the favour of receiving thrice as much space as Russia, which is actually dismissed in only eight pages, whilst France, Germany, Italy, and Spain have only four pages each. Does the Russian Empire, or Spain, with their variety of climate, of soil, and of population, afford less interest for the general reader than Asiatic Turkey, and Italy less than Senegambia or Liberia?

It is obvious that such a distribution of space must affect the entire value of the work. Certainly when reading Mr. Brown's book we have admired in many instances the talent with which he succeeds in condensing in to very few pages a good description of a country; but the book being intended to afford more interest to the general reader than a simple text-book of geography, the author has been compelled to enter into generalisations which cannot but give a false idea of the subject. Is it possible that the reader can have a true conception of the climate of France when he learns from Mr. R. Brown's book that "the climate is one of the finest in Europe—mild, equable, and healthy, in spite of the hot winds from Africa, which sometimes impinge on the southern districts, and the chilly 'mistral' which sweeps down from the Alps in the north"? Or, what an idea will be impressed upon his mind of Paris, when he learns only that "in Paris centres the most polished society of the world. From Paris are sent forth *the books, the bonnets, the pictures*, and possibly even the vices which are so largely aped by the rest of the civilised world. It is the city of pleasure. But, contrary to the general impression, the morals of Paris, if not high, are not superlatively low; for though these are depraved enough, they are infinitely superior in many respects to those of Vienna, Naples, Bucharest, and even Berlin, which is more cir-

cumspect and prudish." All this is quite right, but is it a description worthy of the great capital of the Continent? The same might be said of all the other countries touched by Mr. R. Brown in this volume. All that he says is quite correct, and we do not find such blunders as are too often found in geographical works. But the necessity of giving the reader a generalisation for the purpose of rendering the book more interesting often leads the author to make such generalisations as give to the reader a most untrue conception of the subject. We must regret that Mr. Brown has been compelled to condense his work in this way, and thus seriously diminish the value of what promised to be a useful and trustworthy compilation.

Phonetik. Zur vergleichenden Physiologie der Stimme und Sprache. By Dr. F. Techmer. (Leipzig: Engelmann, 1880.)

THE excellent work on the Physiology of Language published by Dr. Techmer under the above title forms the first volume of an Introduction to the Science of Language, the rest of which is hereafter to appear. We have little hesitation in saying that it is the best *résumé* that exists at present of what is known about the nature and formation of the sounds we utter.

Dr. Techmer has been well prepared for the task he has undertaken. In the first instance a student of natural science, he next devoted himself to the acquisition of modern European languages, then of languages so remote from ours as Chinese and Sanskrit, and finally to the study of comparative philology. Naturally, however, his earlier studies had inclined him rather to the investigation of the material of speech than to the antiquarian researches of the Indo-Germanists or the psychological inquiries of the school of Steinthal. He brought to the investigation a well-trained mind, an intimate acquaintance with physics, acoustics, and physiology, a wide range of reading, and keen observation. What he has to say, therefore, is well worthy of attention.

The ground he covers is so extensive that in order to bring his work within manageable compass he can do little more than indicate the chief facts, methods of investigation and results which have been arrived at by previous phoneticians, along with copious references and notes. These will enable the reader to follow each particular point into special detail, if he so wish. At the same time Dr. Techmer has not been content with being merely a passive reproducer of the opinions of others. He has carefully tested them wherever it has been possible, and made independent experiments of his own, the results of which he lays before us. Hence his judgments and criticisms are always of value, while the numerous and carefully-drawn illustrations and diagrams which accompany his work leave little to be desired.

He has done well in not forgetting the comparative method in his treatment of phonetics. Properly to understand the physiology of human speech it is necessary to compare our vocal organs with those of reptiles, mammals, and more especially birds. Jäger has already been struck by the curious relationship that seems to exist between the power of speech and walking on two feet, and has endeavoured to explain it, though not very successfully.

Perhaps the fact that is most brought home to our minds by a study of Dr. Techmer's book is the uncertainty and obscurity that still hang over a large part of phonetics. Experts still differ radically on some of the most fundamental details of the science. This is more especially the case with that side of the science which has to do with acoustics; on the physiological side it lends itself more readily to observation and experiment, and the physiological conditions requisite for the production of particular sounds are consequently much better known. Hence it is that the nature of the consonants is far more accurately determined than that of the vowels, and that it will be long before all the difficulties connected with the formation of the latter are satisfactorily removed. The best means of overcoming them will be a succession of works like this of Dr. Techmer's, at once clear, precise, and thorough.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Medusæ

IN Mr. H. N. Moseley's "Notes by a Naturalist," on the *Challenger*, p. 404, a curious habit of Medusæ in the Island of Santa Cruz Major, is mentioned, viz. their lying on the tops of their umbrellas, its tentacles directed upwards. I think your readers may be interested to learn that I have frequently noticed Medusæ in a similar position in the West Indies. A few years ago I was quartered for some time at Port Royal, Jamaica, and in the channels between the mangroves I observed what I at first thought were Actineæ of large size on the muddy bottom, in about eight feet of water. They were very numerous. I stirred one up with the boat-hook, and was surprised to find it was a Medusa turned upside down. On being disturbed, it lazily contracted its umbrella in the usual manner and settled down again in the mud as before. The species was about a foot in diameter of umbrella, and dirty white in colour. I never saw them swimming in the mangrove creeks, though I was frequently out in a boat, and they were at all times common on the bottom, lying as described. Some time afterwards I saw what seemed to be the same species at St. George's Bay, a small island about ten miles from Belize, Honduras. It was lying in the same position on the mud amongst the mangroves, in about four feet of water. I poked several up with a stick, and they slowly swam for a short distance, and again settled down on their umbrellas. I believe it to be really the habit of the species to lie on its back, as it were, and it is interesting to find another kind in the east acting similarly. Mangrove swamps are extensive in the vicinity of Singapore, but I have not noticed any Medusæ here in that position, possibly because there is a considerable tide which leaves the mud bare at low water.

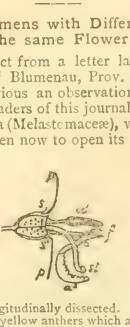
I think I have seen the habit noticed in some book, but cannot recollect where. H. ARCHER

Fort Canning, Singapore, June 28

Two Kinds of Stamens with Different Functions in the same Flower

THE following extract from a letter lately received from my brother Fritz Müller (of Blumenau, Prov. St. Catharina, Brazil) contains so new and curious an observation that it will probably interest the botanical readers of this journal.

"A species of Heeria (Melastomaceæ), which is not indigenous here, begins in my garden now to open its beautiful red flowers,



Flower of Heeria spec., longitudinally dissected. *s*, sepals; *p*, petals; a^1, one of the conspicuous yellow anthers which attract the insects; a^2 one of the inconspicuous red anthers, which powder the insects with pollen; *c*, connective of this anther; *f*, fork of this connective; *st*, stigma.

remarkable for having two kinds of differently coloured anthers. The four petals spread in a perpendicular plane; the yellow anthers (a^1) of the four shorter filaments, closely pressed together, project from the middle of the flower; their bright yellow strikingly contrasts with the violet-shining light red of the corolla; the longer anthers (a^2) are red, like the filaments, and the very long connective (*c*), which is lengthened beyond the point of insertion

into a fork (*f*), with two yellowish points; these points stand close beneath the yellow anthers, whilst the apical apertures of the red anthers (a^2) are placed far below them near the stigma; also the style and the stigma (*st*) are coloured so very like the corolla, that from some distance neither they nor the longer stamens can be seen at all. Any large bee (like Xylocopa, Centris, or Bombus), when working on the smaller anthers in order to collect pollen, would, by moving the connective fork of the larger ones, press the apertures of the latter against the ventral side of its abdomen and powder it with pollen. Until now I have only seen a little fly (Syrphidæ) and *Trigona ruficrus* visiting this flower, both too small to fertilise it. The fly takes only notice of the yellow anthers; the Trigonas, too, always sit down first on these; but most of them (the more experienced specimens?) turn then round, and go to the larger anthers, which offer a more copious pollen-store, and work on them with their mandibles or eat them up entirely. Even if larger bees acted in the same manner as *Trigona ruficrus*, they would have powdered the ventral side of their abdomen before going to plunder the latter. The pollen of both kinds of anthers is white."

HERMANN MÜLLER

Palæolithic Implements in the Thames Valley at and near London. Their Comparative Numbers

IN my former letters, NATURE, vol. xxiii. p. 604, vol. xxiv. p. 29, I cited instances of the occurrence of these objects at great heights, indicating great antiquity, at the north and south of London. After the positions of the implements on the different old river terraces are considered, their numbers, as compared with the amount of material excavated, is a subject of considerable interest, as these numbers indicate in a broad way the amount of human population.

Before I give the results of my own experience I may say here that I have had these implements in view for about twenty years. I have not searched for them myself during all this time, although at first I commonly looked over pits and roads for implements and flakes with little or no result.

I had four reasons for beginning a thorough examination of the London gravels:—1. I had long taken a great interest in the subject. 2. I had particularly noticed the implement found in Gray's Inn Lane now in the British Museum, I had looked over Col. A. Lane Fox's collection from Acton and Ealing, and I knew of two implements from the gravels excavated near my own house. 3. I felt disappointed at not meeting with Thames valley implements myself. 4. I had been unwell through overwork, and my doctor told me I should not be well again till I regularly took a four-miles daily walk.

In the early spring of 1878 I determined to walk over the London gravels and note the constituent stones—not walk over the roads and pits once or twice, but ten, twenty, or if need be fifty times, so as to thoroughly acquaint myself with the stratification and materials.

I began in May, 1878, to examine the excavated gravel at Clapton, N.E. London, in the valley of the Lea. Here, after considerable searching, I found an implement and several flakes. I then mapped out the gravels for twenty-seven miles in a line east and west of North London, and wherever the gravel has been exposed in these twenty-seven miles I have been over it a great number of times. In three years—from May, 1878, to May, 1881, I found exactly one hundred implements, mostly lingulate examples (a few ovate), and thirteen trimmed flakes, *i.e.* genuine implements, but worked on one face only. This is equal to one hundred and thirteen perfect specimens. I also found twenty-one butt-ends and six points, some broken in Palæolithic times, others showing modern fractures; side-scrapers, six; flakes about one thousand four hundred; broken fossil bones, teeth, and tusks, chiefly mammoth and horse, not uncommon. Hammer-stones of quartzite, with abraded ends, none. An unabraded quartzite pebble, such as the pebble mentioned by Mr. Perceval, teaches nothing. Even if one end is abraded off, it might have been rubbed off by other pebbles passing over it whilst naturally fixed in the bed of a stream. When both ends of a quartzite pebble are abraded *quite away*, and the abraded parts are of a *distinctly different colour* from the rest of the pebble, such a stone is probably a hammer-stone. I have several genuine examples of these of Palæolithic age, but not from the Thames valley.

On reading these notes some persons may be inclined to exclaim, What a large number of implements! How common these objects must be! My reply is they are by no means common, but as a rule *extremely rare* and *most difficult to find*. One seldom sees a first-class implement resting flat and clean in the middle of a road or pit, inviting the passer-by to pick it up. They are usually half-buried, with only part of the point, edge, or butt visible, and that part frequently covered with clay or dirt, so that it requires a sharp and trained eye to distinguish the implements and flakes from the ballast with which they are incorporated.

My first attempts were to find how many implements occurred in a hundred tons of London gravel, but I found it impossible to determine this with certainty; I however could accurately find how many miles of the actual drift I had walked over, and my experience is that I walked in three years over four thousand five hundred miles of gravel to find one hundred and thirteen implements, equal to a walk of about forty miles for one implement.

Of course the implements may be more frequent in some places, as at Milford Hill, Salisbury, and Warren Hill, Mildenhall, and much less frequent in others, but the above statement is my personal experience in the twenty-seven miles of river-gravel to the north of the Thames at London. The men working in the roads and pits often questioned me, and I set all the men to look for the implements during my absence: the whole of the men together in three years produced twenty-two extra implements, ovate or lingulate, and worked on both sides.

The mere accumulation of implements was by no means my object. I felt from the first that to entirely depend upon workmen was a great mistake, as all ill-defined instruments must be lost. I therefore personally looked out for genuine new things, and especially wished to ascertain, if possible, what the implements themselves had to teach of the *men who made them*, how the implements were deposited, and if possible to calculate their age in years. With these objects in view I have kept a manuscript book, giving the exact circumstances of finding of every implement in my collection, not only in reference to the implements belonging to the Thames Valley, but to nearly all the implementiferous river-valleys of this country. With equal care I have kept a list of non-implementiferous positions, and my experience is, the lower gravels of the Thames as at Hammersmith and Battersea are barren. As soon however as a seventy or eighty feet terrace is reached, the implements and flakes crop up. Two implements have been found in the Thames at Hammersmith and Battersea, as recorded by Mr. Evans ("Stone Implements," p. 528), but these, of course, were washed out of a higher bed. I have found several flakes and an implement at Clapham Common and Battersea Rise, but here the heights are seventy to ninety feet. The most persistent searching at Lower Battersea and Hammersmith has produced with me absolutely nothing. With your permission I will give further results in a future letter.

THE COMET

WE have received the following further communications on the lately-visible comet:—

THE appearance of a large comet has afforded an opportunity of adding to our knowledge of these bodies by applying to it a new means of research. Owing to the recent progress in photography it was to be hoped that photographs of the comet and even of its spectrum might be obtained and peculiarities invisible to the eye detected. For such experiments my observatory was prepared, because for many years its resources have been directed to the more delicate branches of celestial photography and spectroscopy, such as photography of stellar spectra and of the nebulæ. More than a hundred photographs of spectra of stars have been taken, and in the nebula of Orion details equal in faintness to stars of the 14·7 magnitude have been photographed.

It was obvious that if the comet could be photographed by less than an hour's exposure there would be a chance of obtaining a photograph of the spectrum of the coma, especially as it was probable that its ultra-violet region consisted of but few lines. In examining my photographs of the spectrum of the voltaic arc, a strong band or group of lines was found above H, and on the hypothesis that the incandescent vapour of a carbon compound exists in

comets, this band might be photographed in their spectrum.

Accordingly at the first attempt a photograph of the nucleus and part of the envelopes was obtained in seventeen minutes, on the night of June 24, through breaks in the clouds. On succeeding occasions, when an exposure of 162 minutes was given, the tail impressed itself to an extent of nearly ten degrees in length.

I next tried by interposing a direct-vision prism between the sensitive plate and the object-glass to secure a photograph which would show the continuous spectrum of the nucleus and the banded spectrum of the coma. After an exposure of eighty-three minutes a strong picture of the spectrum of the nucleus, coma, and part of the tail was obtained, but the banded spectrum was overpowered by the continuous spectrum.

I then applied the two-prism spectroscope used for stellar spectrum photography, anticipating that, although the diminution of light would be serious after passing through the slit, two prisms, and two object-glasses, yet the advantage of being able to have a juxtaposed comparison-spectrum would make the attempt desirable, and, moreover, the continuous spectrum being more weakened than the banded by the increased dispersion, the latter would become more distinct.

Three photographs of the comet's spectrum have been taken with this arrangement with exposures of 180 minutes, 196 minutes, and 228 minutes, and with a comparison spectrum on each. The continuous spectrum of the nucleus was plainly seen while the photography was in progress. It will take some time to reduce and discuss these photographs and prepare the auxiliary photographs which will be necessary for their interpretation. For the present it suffices to say that the most striking feature is a heavy band above H which is divisible into lines, and in addition two faint bands, one between G and *h*, and another between *h* and H. I was very careful to stop the exposures before dawn, fearing that the spectrum of daylight might become superposed on the cometary spectrum.

It would seem that these photographs strengthen the hypothesis of the presence of carbon in comets, but a series of comparisons will be necessary, and it is not improbable that a part of the spectrum may be due to other elements. HENRY DRAPER

271, Madison Avenue, New York

My first view of the comet was on June 25, when it appeared through a momentary opening in the clouds, with a nucleus that, in size and brightness, seemed to equal Venus at her best. The tail, immediately at its commencement, was exceedingly bright also, but I could see no more of it then, nor at a second view, also momentary, when little more than the head was visible. Notwithstanding the immense development of tail shown by the great comet of 1861 it could not compare for an instant in brightness with the nucleus of the present one as I saw it on June 25.

On June 27 I again observed it wonderfully waned in light, with a tail plainly traceable for ten degrees, and pointing directly to the Pole. The tail was slightly curved to the right; that is, it was convex to the apparent east, or on the preceding side, and was brightest and best developed on that side. There was no time for observation with the telescope when the clouds shut up the skies for the remainder of the night.

On the next night, the 28th, I got a view with the telescope, and by an observation, which was much interfered with by clouds, I made out the position to be, in Right Ascension, 5h. 58m. 44s., and in Declination 63° 12′ 53″, at 12h. 15m. Greenwich mean time. The comet was progressively waning, but the tail seemed still about 10° long, and pointed to the Polar star. The nucleus, though growing smaller, was still exceedingly brilliant, and as large as a star of the first magnitude. The direction of the tail did not differ very much from the comet's apparent course, and seemed *concave* to it, contrary to what is usually observed with other comets. With a power of 126 on a 4½-inch achromatic I saw a curve of light extending like wings on each side of the head, and outside, with a dark space between them, appeared a large enveloping curve of inferior brightness. I fancied at times that I could discern a very faint third envelope outside all. These curves extended farther in the direction of the tail on the *following* side than on the other, though it was on the latter or preceding side that the tail showed the best definition.

On July 8 the comet seemed much diminished in light and magnitude, though the nucleus was still brightly stellar. I could now see only the inner light-curve extending on both sides of the comet's head, and through it on the following side I distinctly observed a small star shining, as it would appear, with undiminished brightness. The preceding side of the tail was still brighter and better defined than the following. I made the comet's position at 14h. G.M.T. = Right Ascension 7h. 49m. 38s, and Declination 79° 27′ 21″.

On July 11 it was still further diminished, and in the bright moonlight there was no longer any light-curve traceable in my telescope. The nucleus however continued remarkably bright and star-like, and there was an extensive nebulosity round it. The tail might be traced by the naked eye three or four degrees. I had on this night a very satisfactory micrometrical observation, but I have not as yet been able to perfectly identify the star of comparison. The calculated light of the comet was scarce more than a tenth of what it was on June 22. It is now fast receding out of naked-eye view, and of little interest except for marking its position. This on July 20, at 12h. 20m. G.M.T., I made to be 11h. 17m. 47s. in R.A., and 82° 9′ 2″ in Declination.

Schæberle's comet is now well in view, and would be visible to the naked eye only for the brightness of the sky where it is moving. The weakest binocular is sufficient to show it, and it is rapidly gaining in brightness. On the 27th inst. it appeared to me with a stellar nucleus and a tail visible for about half a degree. I made its position at 14h. 15m. G.M.T. = 6h. 14m. 41s. R. Ascension, and 43° 59′ 10″ in Declination. The observation was difficult owing to the brightness of the sky and to clouds.

Millbrook, Tuam, July 28 J. BIRMINGHAM

A POPULAR ACCOUNT OF CHAMÆLEONS[1]

THE animal to which I propose especially to direct your attention to-day is one which has been the subject of many observations, and has inspired great interest from the most ancient times.

Its name "chamæleon" is derived from two Greek words signifying "Ground-lion," a name singularly inappropriate, since it is one of those creatures which are specially fitted by their organisation to live on trees, and which are comparatively ill at ease when on the surface of the earth.

It is by no means surprising however that this creature should have attracted the attention it has attracted, such is the singularity of its appearance and the peculiarities of its habits and properties. Neither is it surprising that it should have occasioned many errors and superstitions when we consider the erroneous beliefs current amongst ourselves with respect to our own toads and slow-worms, efts, &c.

Aristotle was acquainted (as was to be expected of him) with the singular motions of its eyes, but even he fell into some curious mistakes respecting it, and he tells us that

[1] Lecture delivered at the Zoological Gardens on July 28, 1881, by St. George Mivart, F.R.S.

it has no spleen and no blood except in the vicinity of its head and eyes.[1]

Pliny is careful to restate these errors, and further tells us that it lives without eating or drinking, and though generally an inoffensive animal, becomes terrible in the dog-days. He also adds,[2] on the authority of Democritus,[3] that it has the power of attracting to the earth birds of prey, so that they become in turn the prey of other animals, and that its head and neck, when burnt on oak charcoal, will cause thunder and rain to occur simultaneously. On the other hand, he rejects as fabulous the Grecian belief that its right leg cooked with a certain herb has the power of making a person invisible; that the thigh of its left leg mixed with sow's milk will induce gout if the foot be rubbed with the compound, and that a man may be made to incur the hatred of all his fellow-citizens by having his gate-posts anointed with a mixture of chamæleon's intestine and the renal secretion of an ape.

Aldrovandus informs us[4] (on the authority of older writers) that if a viper passes beneath a tree in the branches of which a chamæleon is perched, the latter will let fall some of its saliva upon the viper, which is thereby killed; and he further tells that elephants sometimes unwittingly eat chamæleons amongst the leaves of the trees on which they feed, and that the meal is a fatal one unless the elephants have recourse to the wild olive as an antidote. Gesner in his History of Animals[5] has carefully collected all these fables.

But though more accurate knowledge has dissipated many errors and destroyed many superstitions with respect to the chamæleon, yet such knowledge, far from detracting from the interest of our subject, has made it more than ever an object of scientific wonder and intelligent admiration.

My duty to-day, as I understand it, is to enable you to give a rational answer to the question, "What is a chamæleon?" and therefore to give you an accurate general notion of what the creature is in itself, and in what relations it stands to the world about it. Let us first look at the animal itself. It has a wonderfully lean and hungry look, and is in fact a hungry animal, and keen in pursuit of its insect prey at the present warm season. Its trunk is often greatly flattened from side to side, though sometimes swollen and inflated. It is never flattened from above downwards (as in so many lizards), but deep and raised up from the ground by the animal's long legs. Its head is large, and, in shape, somewhat triangular when seen in profile, and its upper surface is bounded on each side by a prominent ridge extending from the muzzle to the hinder part of the head or occiput. There is hardly any neck externally distinguishable. The limbs (of which there are two pairs) are long, uniformly slender members, each terminated by a paw in the form of a pair of pincers. There is a very long tail, also slender and curled towards its extremity, so as to be able to grasp firmly any object about which it may be rolled. The skin is rather soft and distensible. It is similar all over the body—not scaly (as in most lizards), but beset with small horny tubercles which become more close-set and flattened along the mid-line of the back and of the belly (where the tubercles project in a serrated manner), and also on the head. The mouth of the animal is very wide, but its lips meet so exactly that when closed the situation of the mouth is not readily distinguishable. The nostrils are small and open, one on each side of the muzzle, a little behind its apex. The eyes are very large, but the prominent eyeballs are covered by skin like that of the body, except at a minute central point where there is a small opening like an external pupil. Thus, instead of two eyelids, as in ourselves, there is one, formed as it were by the almost complete junction of two such as ours.

What is however much more remarkable than the form of the eyes is the manner in which they can be used. When we look at any object our eyes always move simultaneously, and are directed as much as possible towards the same object. We can thus make them converge, and we can restore the axes of our eyes to a parallel position, but we cannot make them diverge or direct one eye upwards and the other downwards at the same time. This limited power of motion in our eyes is with us innate and natural. Indeed such is the tendency to simultaneous action in our own eyes, that the very eyelids of our two eyes naturally move together, and it is only by repeated efforts that we obtain the power of moving them separately. The art of winking, then, is not an original gift but an acquired accomplishment, and this is especially the case with that refined winking which consists of a scarcely perceptible motion of the upper eyelid only.

In the chamæleon the motion of the eyes is not thus limited. It can move them with complete independence, and can simultaneously direct one eye upwards and forwards while the other gazes downwards and backwards. As far as I am aware, the chamæleon is the only animal which possesses this power.

But the chamæleon's eye has a very noteworthy internal structure. In ourselves the special organ of sight is an exceedingly delicate membrane called the "*retina*," which is spread out over the back of the inside of the eyeball. This membrane is composed for a part of its thickness of certain most minute structures termed "*rods* and *cones*," which are placed side by side, one end of each being directed outwards, and its other end towards the interior of the eyeball. At that part of the human retina which is directly opposite the pupil of the eye, is what is called "the yellow spot," which is the seat of our most acute sense of vision. In this yellow spot of ours there are many cones but few rods,[1] and the centre of it is formed of cones only. The cones of the yellow spot, moreover, are longer than those found in any other part of the retina.

According to Heinrich Müller, who has most carefully investigated the structure of this animal's eye,[2] the retina of the chamæleon has cones only, but no rods (like the centre of our yellow spot), while its cones are longer even absolutely (and therefore greatly longer relatively) than are our own. Finally the yellow spot itself is larger in the chamæleon than it is in us. Thus in all these respects the perfection of the human eye is exceeded by that of this very singular reptile.

That the chamæleon is able to gaze simultaneously at two distinct objects placed wide apart is not wonderful, because there are so many animals with eyes placed so completely on opposite sides of the head that many objects within the range of one of their eyes cannot possibly be seen simultaneously by the other. But even we are able to direct our attention simultaneously to two objects which lie towards opposite margins of our field of vision, while we neglect the sense impressions produced by all the various intermediate objects.

There is no external sign whatever of an ear in the chamæleon. Not only is there no projection, but there is no external aperture on the surface of the head, or any indication of the drum of the ear—an indication very commonly found in animals nearly allied to it. Nevertheless the chamæleon has a pair of ears substantially like those within our own skull, and these ears each communicate with the exterior by an aperture at the back of the mouth, as do ours also. It is this communication between the internal ear and the mouth which causes a man to open his mouth when he is intently listening.

[5] See his "Historiæ Animalium," book ii. p. 2. The work was published in 1554

[1] In the rest of the human retina the rods are much more numerous than are the cones.
[2] See *Würzburg naturwiss. Zeitschr.*, iii. 1861, pp. 10-42.

The chamæleon's internal ear however is not an exceptionally perfect organ like its eye. On the contrary, an important part, resembling a snail's shell in form, called the cochlea, which is largely developed in us, and which exists in a rudimentary manner in lizards generally, is absolutely and entirely wanting in the chamæleon.[1]

The tongue of this animal is the most wonderful of all its organs, and the chamæleon's entire organisation may be said to have been formed with reference to this most remarkable tongue.

If the animal's mouth be opened, its tongue will be seen as a thick fleshy mass lying between the two sides of the lower jaw. At the front end of this tongue is a cup-like depression with a prominence specially developed above and below it like an upper and lower lip. But this thick portion of the tongue thus at first visible is but a part of the entire structure. At its hinder end it suddenly narrows into another very long and cylindrical part, which is arranged and bent in transverse folds behind and beneath the thick part first described. This narrow part or, as it is called, "worm," finally bends to the front end of the lower jaw, where it becomes continuous with a third firmer part, which is rigid, because it contains a solid body within. This third part reaches from the front of the lower jaw to the back of the floor of the mouth, where it enters a sort of funnel-like depression, to the bottom of which it is firmly attached by flesh and membrane. The cavity of the mouth is very deep, as is necessary for the reception within it of this very voluminous tongue. When the tongue is elongated it may be extended six or seven inches. The action of the tongue will be spoken of in connection with what I have to say as to the other actions of the chamæleon.

The structure of the chamæleon's feet is very noteworthy. Each foot is (as has been said) practically a pair of pincers, but each branch of each pincer is made up either of two or of three toes bound together by the skin down to the very roots of the claws.

There are five toes or (as they are technically termed in anatomy) "digits" to each foot, and these five digits correspond with our own thumb and four fingers and our own five toes respectively.

In the fore-paw or hand of the chamæleon the digits which answer to our thumb, index, and middle digits are bound together in one bundle, while the digits answering to our ring and little fingers form the other bundle.

In the hind-paw or foot of the chamæleon the arrangement is different. There the digits which answer to our great and second toes are bound together in one bundle, and are opposed to another bundle formed of the third, fourth, and fifth toes.

Moreover while the three united digits of the fore-limb are directed inwards, the three united digits of the hind-limb are directed outwards.

There is yet another noteworthy point as to the structure of the paws. In ourselves the small bones which form our "wrist" and our "ankle" respectively are (as they are in almost all beasts) distinct and separate from those long, more or less slender bones which are in the palm of the hand and the sole of the foot, and which are called "metacarpal bones" in the hand and "metatarsal bones" in the foot. In the chamæleon however each metacarpal and each metatarsal absolutely unites with the wrist or ankle bone which is adjacent to it, so that they together form but one bone.

As to the internal organs of the chamæleon, I will only speak of the lungs. These organs are practically a pair of bags—air-bags—but each bag is furnished with seven or eight tubular prolongations, which seem each to end in a point. These ends however really open into certain sacs within the cavity of the body, which sacs can thus be inflated and the whole body much blown out.

[1] See Prof. Parker's paper in the *Transactions* of the Zool. Soc., vol. xi. p. 102.

The last structure I shall notice is the skin, so remarkable for the very conspicuous changes of colour it undergoes. The chamæleon's skin, like the skin of other animals, is furnished with very minute bags containing pigment. It is the presence of very many such bags containing a dark pigment which makes the negro's skin black. These pigment-bags are called "chromatophores," and the chromatophores of the chamæleon, unlike those of the negro, are contractile, and it is by the alternate contraction and expansion of chromatophores containing different coloured pigments that the changes of colour which take place in the chamæleon's skin appear to be effected.

The chamæleon does not make at all a bad pet. It is not only perfectly inoffensive, but most gentle and not at all wild, while it forms an object very interesting to contemplate. It needs to be kept warm and supplied with flies, mealworms, or other insects, and also with water, and with some branching shrub on which it may perch and climb. It is better to inclose the shrub in a glass case or cage, to prevent such accidents as happened to one of mine, which, being left alone and free, wandered to the fire-place, where it got beneath the grate, and so scorched its paws that it could no longer climb, and soon died.

Wonderful is the slowness with which the chamæleon ordinarily moves. When at rest it clings to the branches by its four paws and prehensile tail. When it wishes to advance it only moves one limb at a time. Let us say it begins by moving the right fore-limb. It first, of course, unhooks that paw, and then, bending the elbow, slowly raises it and holds it suspended a certain time, moving it right and left, forwards and backwards, till it finds a suitable foothold. Then its pincer-like fingers slowly and firmly grasp the new point of support, after which the left hind-limb performs a similar series of movements; then follows the left fore-limb, afterwards the right hind-limb, and finally the tail is unrolled, and then readjusted round some new sustaining object.

This is its ordinary mode of progress, but it can sustain itself by its tail only, and when thus hanging may seek for fresh foothold by stretching in various directions all its four limbs.

The chamæleon is probably the most thoroughly arboreal animal which exists. Many creatures of different kinds which live in trees are furnished with a prehensile tail. This is the case, for example, with the most arboreal monkeys, such as the spider- and howling-monkeys. It is also the case with that most arboreal member of the raccoon family, the kinkajou, and with the most arboreal members of the porcupine family and of the opossum order.

Arboreal animals may have their feet especially organised for climbing, as is the case with monkeys and opossums, but they are not such perfectly and exclusively climbing organs as are the chamæleon's feet. The sloths are animals the whole organisation of which is planned for tree-life, and their paws are modified to serve almost exclusively for climbing, and their digits are also bound together by skin to the roots of the claws. Moreover, in the sloths the wrist and ankle bones may more or less coalesce with the metacarpals and metatarsals, as in the chamæleon; nevertheless the sloth's digits are not pincers, but hooks only, all the digits of each foot being bound together in a single bundle. Moreover, admirable as is generally the arboreal organisation of the sloth, that animal is nevertheless devoid of a prehensile tail.

In birds the ankle-bones coalesce with the metatarsals, and there is a certain resemblance between the feet of the climbing arboreal parrots and those of the chamæleon, for though the parrot's toes are not bound together to the claws, they yet form a pair of pincers, two of them being turned in one direction and opposed to the other two Yet the mode in which they are grouped is different. for

in the parrot it is the first and fourth toes which are opposed to the second and third, instead of the first and second to the others.

In remarkable contrast with the slowness of its limb-movements is the quickness with which it can move its eyes, and above all its tongue. The chamæleon lives largely upon flies, and at first sight it would seem impossible that so apparently torpid and sluggish an animal should be able to reach and seize creatures not only active in their movements, but possessing the power of flight. At this season, when the chamæleon's appetite is keen, it may often be observed when a fly has been introduced into its cage to move about with comparative celerity, attentively watching the fly's movements, now with one and now with the other eye. It sooner or later happens that the fly settles for a few seconds somewhere within half a foot's distance of the chamæleon's head. Then the chamæleon's mouth may be observed to open and the apex of the tongue to protrude. In an instant it has shut again and the fly has disappeared. In fact the chamæleon has spit out, as it were, its enormously extensible tongue upon the insect, secured it by the viscid secretion with which the tongue is coated, and again withdrawn that organ together with the prey, but the whole has been effected with such amazing rapidity that the observer's eye cannot follow the movements of the reptile's tongue. It is projected and withdrawn without the slightest noise, but in the twinkling of an eye.

As I have said, it is this tongue which is as it were the centre of the chamæleon's organisation, and this tongue-movement is the very essence of its existence, and is its whole *raison d'être*. Without it the animal's life would be impossible, while the very slowness and deliberation of its other movements are a gain, since they enable the chamæleon to advance upon its prey within shooting distance without alarming it.

(*To be continued.*)

THE UNEXPLORED PARTS OF EUROPE AND ASIA

UNDER this title M. Venoukoff has just published an interesting paper on those parts of Europe and Asia which remain yet unexplored. It is not to be wondered at that the name of Europe should be among incompletely explored parts of the world, as there are even in Europe considerable spaces, especially in the Balkan peninsula and in North-Eastern Russia, which await scientific exploration. The war of 1877-78 certainly afforded occasion for surveying and mapping wide spaces in Bulgaria and Eastern Roumelia, but the geography of Macedonia, Epirus, and even of Thessaly is far from being exact. In Russia all the northern provinces, from the Norwegian frontier to the Ural Mountains are only known superficially; we know here only the coast and the three principal rivers—the Onega, the Dwina, and the Petchora. The great Samoyede *tundra* remains quite unexplored. Notwithstanding several journeys in the Northern Ural, this country is little known, and the interior of the great double island of Novaya Zemlya remains quite unknown, both affording, however, a very great interest, especially for geologists. As to the hydrographical exploration of the Kara Sea and of the Arctic Ocean north of Siberia, M. Venoukoff does not give them much of importance, notwithstanding what he terms the pompous newspaper writing about the trade with Northern Siberia, and he thinks that there are on the Asiatic continent several places far more interesting for explorers. For instance, Chekanovsky's and Nordenskjöld's explorations have quite changed our ideas on the geography of that land, twice as wide as France, which belongs to the basins of the Khatanga and of the Anabara. It would be a rich field of exploration for a bold traveller. The lands east from the Lena remain quite unknown, and the northern slopes of the Stanovoï Mountains are still a *tabula rasa;* the sources of the Indighirka, Kolyma, Omolon, Aniouy, and Ghijiga rivers were never visited by Europeans, and Wrangel mapped them only from hearsay. The land of the Chukchis is better known, thanks to the work of the explorers of the last century, to the recent Russian expeditions, and to Nordenskjöld's information; but all our knowledge of this country is far from being exact, and Europeans have never penetrated to the interior of the peninsula which separates the Arctic Ocean from the Pacific, and which promises to have a future as a meeting-point for the whalers, as well as for the trade in mammoth bones. The land of the Koriaks is less attractive, except for a naturalist. As to Kamchatka, certainly it is passably well known, but what a mass of work remains to be done in mapping the west coast, preparing a map of the interior, studying the most interesting geology, botany, and ethnography of the peninsula! Further south we see that the northern part of Sakhalin remains quite unexplored; the Sikhota-alin Mountains are all but unknown; and the regions between the Ussuri and Sungari Rivers, the sources of the Nonni and Argoun Rivers promise very much to the naturalist and to the geographer who would study them. The interesting peninsula of Corea will certainly be explored as soon as access to it is not forbidden to Europeans. In the Chinese Empire there are spaces as wide as England which remain unexplored. As to Eastern and Northern Thibet we are not yet sure as to what is the true source of the Brahmaputra and of the Irawaddi, and what is the importance in the orography of this land of the Kuen-Lun range. The inaccessible deserts of Eastern Turkestan are as deserving of exploration as Thibet, and the reaching of the sources of the Hoang-ho is one of the *desiderata* of geographical science. The great desert of Gobi is passably well explored, but still there remains an important problem: Does there exist, under the 42° and 43° N. lat., a chain of mountains which crosses the desert and unites the eastern Thian-Shan with the In-Shan Mountains? In northern Mongolia there still remain unknown the highlands at the upper parts of the Selenga River. In China proper there is certainly no room for geographical discoveries, but there remains very much to do as to astronomical determinations, and the substitution of a true picture of nature for the hypothetical chains of mountains which cover our maps. Useless to speak of what might be done with regard to the ethnography of Western and South-Western China. A most attractive exploration would be certainly that of Indo-China in all directions, but it is to be feared that such an exploration will remain for a long time a simple dream, because of the political institutions of this terrestrial paradise. But the exploration of Siam and Annam is one of the most necessary geographical *desiderata*. Without speaking of the Asiatic islands, where so much remains to do, M. Venoukoff points out that British India is certainly one of the best explored countries in the world, and that several parts of Europe are far behind India as to our geographical knowledge of them; but it is not the case as to those countries which are situated to the north-west of India. Afghanistan and Beluchistan await explorers, especially for certain, perhaps the most important, parts of them, as well as Southern Turkestan and the land of the Turkomans, where so much remains to do. Khorassan and Western Persia are quite well known, but Iran remains unknown; of course the exploration of these deserts, as well as of those of the interior of Arabia, would afford very great difficulties and give comparatively few scientific results. But a thorough geographical exploration of Armenia and of Asia Minor is most desirable; and, to finish with Turkey, M. Venoukoff asks if the Straits of the Hellespont and Bosphorus will

be seriously explored as to the most important question of the existence of an undercurrent in these straits?

As seen from this short sketch, there remains plenty of work for geographers and naturalists on our continent, and we may only express the wish that M. Venoukoff's idea of publishing a sketch of the "Unknown Lands," with a summary of the most important questions with regard to them, were executed on a larger scale, and that such a compendium were put into the hands of every young geographer.

NOTES

WE heartily commend to the attention of our readers the announcement of the Rolleston Memorial Committee, to be found in our advertising pages.

THE Scottish Zoological Laboratory, which last year supplied Mr. G. J. Romanes and Prof. Ewart with the material for their researches on Echinodermata, published in the Croonian Lecture, is this year to be placed at Oban. Those who intend to avail themselves of the advantages held out by this institution for the purposes of original work, are requested to communicate with Prof. Ewart, the University, Aberdeen.

THE accommodation for anatomical work at the Prosector's rooms in the Zoological Society's Gardens, which has hitherto been somewhat limited, has lately been increased by the erection of three new working-rooms, intended for the use of students. These rooms are now finished, and are at present tenanted by a small Long-Vacation class from Cambridge, who, under the superintendence of Mr. T. T. Lister, the Demonstrator of Comparative Anatomy in that University, are studying practically the anatomy of the *Mammalia* on the abundant material in that group provided by the Society's Menagerie. The class, it may be remarked, includes two lady students from Newnham College. It is to be hoped that when this class concludes its labours at the end of the month, other students may be found disposed to profit by the new facilities for work afforded them by the Zoological Society, and that thus the expense incurred in the erection of these new rooms may be fully justified by the increased scientific results reaped in the Regent's Park from the superabundant material at the disposal of Mr. Forbes.

THE honour of Knighthood has been conferred upon Mr. F. J. Bramwell, C.E., F.R.S., for his services to technical education.

THE German Emperor has conferred on Dr. Schliemann the Prussian Order of the Crown of the Second Class.

THE death is announced, at the age of seventy-seven, of Mr. Hewett Cottrell Watson, the well known English botanist.

DR. FERDINAND KELLER, the well-known Swiss archæologist, died at Zurich on July 21, in his eighty-first year. Dr. Keller had a decided taste for science in his youth, and shortly after leaving the University went to Paris, where he spent some time in the study of natural history. In 1832 he discovered a number of Celtic grave-mounds on the Burghölzli, a circumstance that led to the formation of the national Swiss Antiquarian Society. Of this Keller was named president, a position that he occupied for many years. The first work of the society was the exploration of the Burghölzli; and other similar researches, which threw much light on the primeval history of Switzerland, were undertaken. In 1837 began the publication of the Society's *Communications*, thirty volumes of which were wholly illustrated, and almost wholly written, by the president. In 1853 he opened the series of researches into the origin of Swiss lake-dwellings which have made his name so widely known, and revealed the way of life, in its minutest details, of a race of men whose mere existence had hardly before been suspected. Between 1860 and 1864 Dr. Keller gave to the world the results of his investigation of the Roman antiquities of eastern Switzerland. He wrote or edited further a history of the Abbey of Zurich, of the arms of Zurich, and sundry miscellaneous papers relating to life and culture in the middle ages. Until past his eighty-first year Dr. Keller continued to be an active and energetic member of the society which he had founded.

THE thirty-fourth summer meeting of the Institution of Mechanical Engineers was opened on Tuesday in Newcastle-on-Tyne, this being the third visit of the Institution to that town. The chair was occupied by the president, Mr. Edward A. Cowper. The president, after some remarks on foreign competition, gave a statement of the result of the progress of mechanical engineering during the past twelve years, and expressed the hope that the latter part of the present century would be marked not only by small improvements, but by many substantial inventions for the good of mankind. Mr. I. Lowthian Bell read an exhaustive paper on the Tyne as connected with the history of engineering, and a paper by Mr. F. C. Marshall of Newcastle, on the progress and development of the marine engine, was also read.

THE *Sydney Mail* brings us the welcome news that the Biological Station has been fairly established at Watson's Bay, under the direction of the well-known Russian naturalist, Dr. Miklucho-Maclay. During the last two years Mr. Maclay has been endeavouring to establish a zoological station in the neighbourhood of Sydney. Being seconded in his efforts by the Royal and Linnean Societies of Victoria and by the Royal Society of New South Wales, he has obtained from the Government an eligible site at Watson's Bay, most appropriate for the purpose. The station is situated on the shallow basin of Port Jackson, and close to the deep water of the Pacific, with large freshwater swamps and lagoons in the immediate neighbourhood, and a vast tract of wild forest country to the north, which probably will remain for a long time to come in its primitive wildness. The communication between Watson's Bay and Sydney by steamer being frequent and rapid (half an hour), the scientific work at the station will be greatly facilitated by the museums, gardens, and libraries of Sydney. The expenses for the building are estimated at 600*l.*, and will be covered by the sum of 300*l.* already allowed by Government and by the subscriptions, whilst the yearly expenses will probably be covered by annual grants of the Linnean and Royal Societies of Victoria and of New South Wales. The building, which stands on a slight eminence overlooking Camp Cove, with lovely views from the balconies on all the four sides, has been constructed to suit the requirements of a biological laboratory. It has five work-rooms, two bed-rooms, a bath-room, and a room for stores, plenty of light being provided for the work-rooms, which are fifteen feet by twelve feet each and twelve feet high. The partitions between each set of rooms are constructed of studding and double-lined, the space being filled with sawdust for the prevention of noise. The trustees are quite satisfied with the building; even upon so humble a scale as the present, it promises to give very good results. It may be hoped that the institution will become a bond of union between all those in Australia who are interested in biological research. As to the expected results we can but repeat M. Maclay's words: "Next after the tropics (which are the richest in animal life) the widest field offered to the investigator of nature, and consequently the most suitable region for the establishment of zoological stations, is Australia, with a fauna so interesting, so important, and so far from being sufficiently known, especially as regards anatomy and embryology."

PROF. C. V. RILEY, chief of the U.S. Entomological Commission, has accepted the position of Entomologist to the

Department of Agriculture, which has been tendered him by the new Commissioner, Dr. Geo. B. Loring. The appointment is to take effect on August 1. It will be remembered that, owing to differences with the retiring Commissioner of Agriculture, Prof. Riley resigned this same position two years ago, and we understand that he accepts it again at a salary less than that which the Members of the Entomological Commission get, because his reinstatement has been so generally demanded by scientific and agricultural associations, and because there is a near prospect, under the new administration, of the department being enlarged in scope and usefulness. Prof. J. H. Comstock, the retiring entomologist, was formerly an assistant under Prof. Riley, and will continue his connection with the department, pursuing the special work on the Coccidæ, which he has more particularly been engaged in. The reappointment of Prof. Riley will meet with approval not only in America, but here, where he has many friends and his work is well known and appreciated.

THE opening of the Exhibition of Electricity at Paris has been postponed as we anticipated. The ceremony will take place on August 11, and numerous speeches will be delivered by the public authorities. The electrical railway is being constructed from the Place de la Concorde to the Porte de l'Est of the Palais de l'Industrie. The posts required for supporting the copper wire required are attracting considerable public notice.

THE steamer *Travailleur* of the French Navy is now engaged in the Mediterranean Sea for dredging purposes, with a regular staff of scientific workers on board.

ONE of the results in Paris of the advent of two comets has been to infuse life into the popular Trocadero Observatory, which is visited by a large number of members, and where a course of lectures on several astronomical subjects is going on.

THE seventh annual conference of the Cryptogamic Society of Scotland will commence at Salen, Island of Mull, on Tuesday, August 30, 1881.

THE arrangements connected with the unveiling of the statue of Harvey at Folkestone on Saturday next, August 6, by Prof. Owen, are now nearly completed. It is expected that there will be a large concourse of doctors and others on the occasion. A small bust of the much-admired head of the statue is now on view in the western gallery of the Sanitary Exhibition at South Kensington, and can be had either in terra-cotta or imitation bronze. A reduction of the whole statue is also contemplated by the sculptor, Mr. A. B. Joy, and will be completed if a sufficient number of subscribers should order it.

IN a *Gazette* covering 250 pages have been published the new Statutes which have been promulgated by the University of Oxford Commissioners.

WE have received *Anthony's Photographic Bulletin* (New York) for June, containing an enlarged copy of Dr. Henry Draper's photograph of the nebula in Orion. The enlargement shows we have very little to hope for in this direction, still the result is a *tour de force* which reflects credit on Dr. Draper. The same number contains an excellent photograph of the Doctor himself.

WE regret to learn that the Committee, formed more than twelve months ago, to raise and present to Dr. William Farr, C.B., F.R.S., a testimonial on his retirement from the public service, have only succeeded in obtaining 930*l*. This sum has been temporarily invested in the names of trustees; and, disappointed as the Committee feel at the comparatively small success of their efforts, they have decided to close the fund so soon as they are able to obtain the small balance now required to raise the amount of the testimonial to 1000*l*. We trust there will at least be no difficulty in obtaining the small sum still required to complete the testimonial.

PHILOLOGISTS will be glad to learn that Prof. G. Beltrame's valuable papers on the Denka language have at last been published in full. They occupy the whole of the current volume of the Italian Geographical Society's *Memoirs*, and consist of three parts, a very complete grammar, an Italian-Denka and a Denka-Italian vocabulary, the former of nearly 4000, the latter of 2000 words. The grammar had already appeared in previous bulletins of the society; but these are now mostly out of print, and in any case the directors rightly considered that students would find it convenient to have all the documents collected in one volume. The Denka is one of the most widespread as well as one of the most interesting of all the Negro tongues current in the White Nile region, being spoken with great uniformity by all the tribes between 5°–12° N. along the main stream and its tributaries, who are collectively known to the Arabs as the Denka nation, but who call themselves *Jen*, a derivative form of *Jan* = race, people. They lie mainly between the Nuêr and Shillûks on the north, and the powerful Bari nation on the south, stretching westwards as far as Dar-Fertit, and southwestwards to the Nyam-Nyam country. There are altogether twenty-five chief tribes, but the common speech presents scarcely any dialectic variety except amongst the Shîr in the extreme south, and amongst the Abuyo and others in the Sobat valley. The language itself is quite distinct from any of the other Upper Nilotic idioms, and is characterised by remarkable regularity and clearness in its structure. It is entirely destitute of grammatical endings, and most of the words are monosyllabic. Prof. Beltrame belongs to a somewhat obsolete school of philologists; hence still speaks of six cases, moods, and other verbal forms. But it is sufficiently evident from his otherwise lucid exposition, and especially from his copious examples, that there are neither cases, moods, tenses, nor, strictly speaking, verbs at all in the language. It need scarcely be remarked that the Denka has nothing in common either with Galla, Ki-Ganda, or other members of the surrounding Hamitic and Bantu linguistic families. It forms one of the numerous independent groups that have been developed during the course of ages amongst the true negro tribes of Sudan and the Upper Nile Valley. Prof. Beltrame's papers must be regarded as a valuable addition to our knowledge of African forms of speech, and will prove of permanent value when the time comes for a more exhaustive study of this ethnical domain.

THE International Pharmaceutical Conference is holding its meetings in London during the present week; one of the questions engaging its attention is an International Pharmacopœia, the desirability of which is generally admitted.

A SLIGHT shock of earthquake was felt at Bangor, Maine, U.S., on July 31.

AT the last meeting of the Natural History Class of the University of Edinburgh, held on Monday, July 25, an illuminated address was presented to Prof. Alleyne Nicholson, of St. Andrews, who has been lecturing on behalf of Sir Wyville Thompson for the past three sessions. The address was signed by about 500 of the students who have attended Prof. Nicholson's lectures during the past three years.

SHORTLY before midnight on July 20 a splendid meteor was observed at Munich. It resembled a fiery ball of 30 centimetres diameter, and it passed slowly from south to north in an almost horizontal direction.

AT the distance of twenty-seven miles north-east from Padang (on the western coast of Sumatra) and some fifteen miles east from Lake Singkarah, we find a high land very similar to the Saxon highlands, and reaching a height of 2400 feet above

the sea-level, the hills of which are formed of sandstones which contain immense coal-fields. According to a description of them, just published by D. D. Veth in the *Deutsche Geographische Blätter*, these coal-fields may contain altogether no less than 300 millions of tons of good coal. The northern, or Parambahan part of them contains two main beds of coal, having an average thickness of thirty-three feet and occupying a surface of about three square kilometres, that is, about 20 millions of tons of good coal; but the rocks are rather disturbed, and therefore the extraction of coal would be difficult. The middle, or Singalut part, situated on the right bank of the Ombilin River, contains about 80 millions of tons of coal, and consists of seven thin beds of coal, which have altogether an average thickness of 16 feet, But the best coal-field is the southern, or Sungei-Durian part, situated on the left bank of the Ombilin River, which contains about 200 millions of tons of good coal. The beds of coal are three, having a thickness of 20, 7, and 7 feet, separated from one another by sheets of sandstone 50 to 70 feet thick. As to the quality of the coal, thirteen tons having been extracted and brought to Padang, it was found that as fuel for steam-engines this coal is not below that of Cardiff or Newcastle, but that it would not be as good as these two in the production of lighting gas or for iron furnaces. As to the transport of this coal to the sea-coast, it would necessitate the construction of a railway 65 or even 100 miles long.

THE Danzig *Naturforschende Gesellschaft*, which numbers now no less than 398 members, has just issued a new volume of its *Proceedings* (new series, vol. v., fascicules 1 and 2). It contains, besides the minutes of meetings of the Anthropological, Physical, Chemical, and Medical Sections, much valuable information, especially as to the botany and zoology of Prussia. The *pièce de resistance* of this volume is an essay at a topographical flora of West Prussia, by H. von Klinggraeff, being a *résumé* of the author's own researches and of what is known on the flora of this province. The author finds that there are in this province no less than 1218 species of Phanerogams, 44 species of cellular Cryptogams, 363 species of mosses, 18 of Characeæ, and 276 species of lichens, and he takes into account only the true inhabitants of the province. As to the lower Cryptogams, the figures are but provisional ones, as the algæ and mushrooms of the province are but incompletely known. We notice also in this volume papers on the freshwater molluscs of the neighbourhoods of Danzig, by E. Schumann; on the Ichneumonids of Western and Eastern Prussia, by C. Brischke; the *Reports* on the third meeting of the Botanical and Zoological Society of Western Prussia, containing a series of catalogues of plants found during botanical excursions; an interesting paper by C. Brischke, which deals with a rather neglected question, namely, with the Phytophags which the author has observed and cultivated in the neighbourhood of Danzig; a paper on the bronze-basin of Steinwage, by Dr. Fröling; and on the Cenoman fossils which are found in the diluvium near Danzig, by Dr. Kiezow.

THE St. Petersburg Naturalist's Society intend to offer various prizes for botanical papers, and to couple with them the name of the late Dr. Schleiden, who was a member of the St. Petersburg Academy and Russian State counsellor.

ON July 21 the meeting of Polish Naturalists and Physicians took place at Cracow. Some 500 members attended the meeting.

ACCORDING to the latest investigations the *Phylloxera vastatrix* has spread enormously upon the peninsula of Istria, particularly in the neighbourhood of Pirano. The plague threatens to infect the vineyards of the Karst, of Friaul, and of Carniola.

WE learn from a circular, issued by the Director of the St. Petersburg Central Physical Observatory, that all the Arctic meteorological stations will soon be opened, and that about the autumn of 1882 we will have observations from these stations for a whole year. The following, we may remind our readers, are the stations to be established:—At Upernivik, by Denmark; in Northern Finnmarken, by Norway; on the Jan Mayen Island, and, if possible, on the western coast of Grönland, by Austria-Hungary; on Spitzbergen, by Sweden; on Novaya-Zemlya (already opened a year ago) and at the mouth of Lena River, by Russia; on Point Barrow and in Lady Franklin's Bay, by the United States. Sites have already been taken by the United States and Norway to open new stations. It is to be hoped that meteorological stations will be opened, according to the wish of the International Conference at Bern, also in Antarctic regions, namely, on South Georgia, by Germany, and at Cape Horn, by France; whilst the Netherlands expect to establish a station further in the Arctic region, namely, at Dickson Haven in Siberia. The International Conference which will be opened at St. Petersburg will establish the method of observation to be adopted at all these stations.

AN International Exhibition is planned for 1883 at Shanghai.

THE additions to the Zoological Society's Gardens during the past week include two Common Marmosets (*Hapale jacchus*) from South-East Brazil, presented by the Lord W. G. Cecil; two Common Squirrels (*Sciurus vulgaris*), British, presented by Mr. C. B. Barber; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mr. Douglas; two Common Jays (*Garrulus glandarius*), British, presented by Mr. Arthur F. Astley; a Common Cuckoo (*Cuculus canorus*), British, presented by Mr. Harry Morrisson; a Surucucu Snake (*Lachesis mutus*) from Pernambuco, presented by Mr. C. A. Craven; two Common Boas (*Boa constrictor*) from South America, presented by Mr. G. H. Hawtayne; a Common Adder (*Vipera berus*), British, presented by Mr. J. Snow; two Blossom-headed Parrakeets (*Palæornis cyanocephalus*) from India, four Common Widgeons (*Mareca penelope*), an Osprey (*Pandion haliatus*), European, purchased; a Guinea Baboon (*Cynocephalus sphinx*) from West Africa, received in exchange. Amongst the additions to the Insectarium during the same time are imagos of *Antheræa yama-mai*, bred from eggs, and larvæ of the Lobster Moth (*Stauropus fagi*), Pebble and Swallow Prominent Moths (*Notodonta ziczac* and *dictæa*) and Purple Thorn Moth (*Selenia illustraria*). Numerous Ant-Lions (*Myrmeleo formicarius*) are also now emerging in the perfect state from their burrows in the sand.

SOLAR PHYSICS—THE CHEMISTRY OF THE SUN[1]

WHAT then are those precise difficulties to which reference has been made?

The number of them is considerable, and they have arisen from careful study extending over many different fields of work.

1. We most conveniently begin by noticing those suggested in the work of comparing the lines of the different elementary bodies with the Fraunhoferian lines; work done chiefly by Kirchhoff, Ångström, Thalén and others. Kirchhoff was not long before he found that to say that each substance had a spectrum entirely and specially belonging to that particular substance was not true. He says,[2] "If we compare the spectra of the different metals with each other, several of the bright lines appear to coincide." Now Kirchhoff was working with Bunsen as his collaborateur, and therefore this was not said lightly, as we may imagine. Similarly Ångström, who was working with the assistance of the Professor of Chemistry at Upsala, was driven to exactly the same conclusion. He says[3]—

[1] Lectures in the Course on Solar Physics at South Kensington (see p. 150). Revised from shorthand notes. Continued from p. 301.

[2] "Researches on the Solar Spectrum." Roscoe's translation. Part I. p. 10.

[3] "Recherches sur le Spectre Solaire," p. 36.

I translate his words—"Of all the bodies iron has certainly produced the greater number of lines in the solar spectrum. Some of these seem to be common with those of calcium." Thalén carried on this work, and if one compares the magnificent tables, which we owe to his untiring skill and industry, one is perfectly astonished to find the number of coincidences which he has so carefully tabulated.

2. There was another kind of work, a newer kind of work, going on. Observers began to give particular attention to the bright lines of flames, and the lines thickened in spots. And here I may limit myself to the general statement that the divergence between the spectra of the different substances as observed in the sun and in our laboratories was very much intensified as facts were accumulated. Very many of the lines observed in flames were lines with no terrestrial equivalents, and the spot-spectrum often contained lines much thickened, which were either not represented at all, or only feebly among the Fraunhofer lines.

3. Next, among all the metalloids known to chemists only one of them—or one substance classed as such, hydrogen—was present in the solar atmosphere, and that in overwhelming quantity; whereas the efforts of Ångström, Kirchhoff, and others could not trace such substances as oxygen, chlorine, silicon and other common metalloidal constituents of the earth's crust.

4. Then again, the layer which was produced by what was taken to be gaseous magnesium round the sun, a layer indicated by the brightest member of the *b* group, was always higher—always gave us longer lines—than that other layer which was brought under our ken by the bright line D seen in the spectrum of sodium.

Here was a distinct inversion of the chemical order. The atomic weight of sodium being 23, and of magnesium being 24, the sodium ought to have been higher than the magnesium; but the contrary was the fact, and that fact still remains after twelve years of observation.

5. As the work of tabulating the lines went on, and the more complex outpourings of vapours from the sun's interior were studied, it was found that the lines of iron, calcium, and so forth revealed to us were by no means the brightest lines—by no means the most important, or most prominent lines, but lines which really we had very great difficulty in recognising as characteristic of any particular spectrum. There they certainly were, however, mapped as very fine lines by the most industrious observers. Similarly with the spots, there was an absolute inversion of the thickness of the lines of any one substance in the spot. Surely there was a great screw loose here.

6. Closely allied to these observations we had another extraordinary fact. We could quite understand why in a spot the change of refrangibility of the magnesium lines when there was a storm going on in the sun should be different from the change of refrangibility of, say, the iron lines. The natural explanation was, of course, this: you have the magnesium gas going at one rate, the iron gas going at another rate, and that is all there is to be said about it. But it was soon found that the differences which could be sharply seen between the spectrum of a particular mass of magnesium vapour and a particular mass of iron vapour extended to the iron vapour itself. There were just as many variations in the refrangibility of the lines of iron itself, for instance, as there were between the lines of iron and other substances: that is to say, we had in the one case magnesium going at one rate and iron going at another rate; but when we came to deal with the iron lines alone we found one

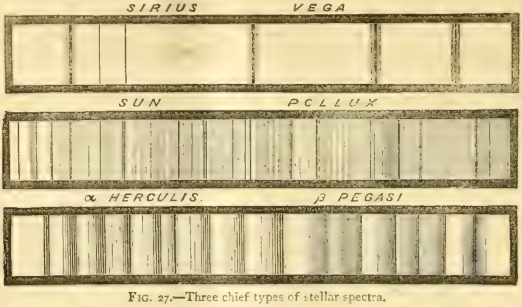

FIG. 27.—Three chief types of stellar spectra.

iron line told us the iron vapour was going at one rate, and another iron line told us that same iron vapour was going at another rate. It will be seen at once that there was a great difficulty in that.

7. Further. The lines on which these observations of the relative motions of the vapour depended were found to go in sets. In a spot, for instance, we would generally see movement indicated by one set of iron lines, whereas in a prominence we would always see a different set—a set in a different part of the spectrum altogether—registering this movement for us. Here again was considerable food for thought.

That was stated very roundly a good many years ago—in 1869. I will read what was then written on this subject:[1] "Alterations of wave-length have been detected in the sodium, magnesium, and iron lines of the spot's spectrum. In the case of the last substance the lines in which the alteration was detected were not those observed when iron, if we accept them to be due to iron alone, is ejected into the chromosphere."

That caveat with regard to iron arose from the fact that of the 460 lines recorded by Kirchhoff in 1869 only three lines of iron had been seen bright in the solar prominences.

8. Then came a point which has been very slightly alluded to already. How came it that the total chemical composition of this atmosphere of the sun, which we were taught to look upon as the exemplar of what must have once happened to our own planet, varied so enormously from the composition of the crust of our earth? No oxygen in it, no silicon, no fluorine; whereas we get abundance of titanium, nickel, and so on. It was difficult to imagine a stronger difference to exist between any two masses of matter than the chemical constitution of the incandescent sun, and of the earth, which is now cooling.

9. There was still another point of view very soon forced upon solar observers by the magnificent success which had attended the labours of Dr. Huggins, Secchi, and other observers in recording the spectra of stars. It was a most interesting inquiry naturally to see whether the stars gave spectra quite like each other, and if it should happen that they did not give spectra like each other, then the points of difference would be sure to give us some excellent working suggestions.

Now what are the facts? Here are three typical stellar spectra (Fig. 27), which show us at once that there is a very considerable difference in the phenomena. In the upper part of this diagram we have a star remarkable for the fewness of lines in its spectrum. From one end of the spectrum to the other there are not above half-a-dozen prominent lines. In the next part however we have a star which is remarkably like our own sun, both as regards the number of lines and their arrangement. In the lower part of the diagram, on the other hand, we have a star in which we get flutings instead of lines; so that we get not only a difference of degree, but a fundamental spectroscopic difference of kind. Now there is a circumstance connected with that first star with the simple spectrum very striking to any one in the habit of observing the sun, and it is this: those lines visible in the star, which, be it remembered, had been independently determined to be hotter than our sun, are precisely those lines, and none other, which we see bright on the disk of the sun itself. I have emphasised the fact that

[1] *Proc.* Roy. Soc., vol. xviii. p. 74.

we have independent evidence that the star with very few lines is hotter than our sun. It is also clear that the other star with the fluted spectrum is a star much cooler than our sun, because it was one of those red stars, the light of which is exceedingly feeble, which, on grounds independent altogether of spectroscopic evidence, are supposed to be stars in the last stage of visible cooling.

So much then for some of the earlier observations on the coincidence of metallic lines in the sun, with observations on the lines themselves in different portions of the sun's atmosphere.

10. We now come to another part of the work where we also find difficulties. Angström, in that exceedingly important memoir which accompanies his Atlas, states:[1] "In increasing successively the temperature I have found that the lines of the spectra vary in intensity in an exceedingly complicated way, and consequently new lines even may present themselves if the temperature is raised sufficiently high." Kirchhoff, on his part, had seen phenomena very similar to those thus touched upon by Angström, but his explanation was a different one. He did not agree that the temperature upon which Angström laid such strong stress was really the cause at work. He attributed those changes rather to the mass and the thickness of the vapours experimented upon—nay, he went further: at a time when scarcely any facts were at his command he broached a famous theorem which went

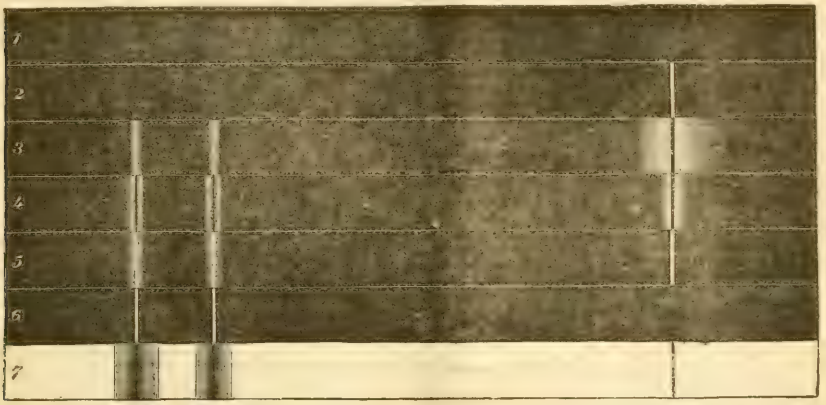

FIG. 28.—The blue end of the spectrum of calcium under different conditions. 1. Calcium combined with chlorine ($CaCl_2$). When the temperature is low, the compound molecule vibrates as a whole, the spectrum is at the red end, and no lines of calcium are seen. 2. The line of the metal seen when the compound molecule is dissociated to a slight extent with an induced current. 3. The spectrum of metallic calcium in the electric arc with a small number of cells. 4. The same when the number of cells is increased. 5. The spectrum when a coil and small jar are employed. 6. The spectrum when a large coil and large jar are used. 7. The absorption of the calcium vapour in the sun.

to prove this; and yet what had Kirchhoff himself done? how had he traversed his own theory? He states that his observations were made by means of a coil using iron poles one millimetre in thickness. Now the thickness of a short spark taken from iron poles one millimetre in thickness would probably be two millimetres. Next Kirchhoff allocated the region where the absorption which produces the reversal of the iron lines took place at a considerable height in the atmosphere of the sun, and he expected the atmosphere of the sun to be an enormous mass represented by the old drawings of coronas, so that on Kirchhoff's view the thickness of the iron vapour which reversed the iron spectrum must have been, at a moderate estimate, 10,000 miles, and yet he said that the spectrum of that, and of the light given by the coil were absolutely identical; that is to say, that the *fact* was that the variation of thickness from two millimetres to 10,000 miles made no difference. That was on the one hand; on the other hand he gave us his *theorem*, showing that a slight variation of thickness would produce all the changes which Ångström and others had observed up to that time, and which we have observed since in much greater number.

A diagram (Fig. 28) will show the sort of changes to which Ångström referred, changes which have been observed by every

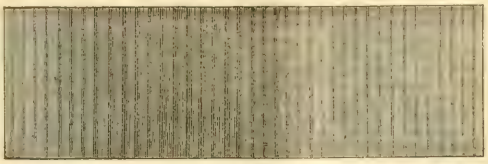

FIG 29.—Fluted spectrum of iodine.

new worker who has taken up the subject. It represents the variations which take place in the spectrum of calcium in the photographic region. At a particular temperature we get a spectrum of calcium which contains no lines whatever in the blue, but when we increase that temperature—the temperature of a Bunsen burner is sometimes sufficient to produce it—we get a line in the blue. When we pass from a Bunsen burner to an electric lamp we get this blue line intensified and reversed, and at the same time we get two new lines in the violet. Using a still higher temperature in the arc, we thin the blue line, and at the expense of that line, so to speak, we thicken the two in the violet, so that the latter equal the blue line in thickness and intensity. Passing to a large induction coil with a small jar we make the violet lines very much more prominent, and using a larger induction coil and the largest jar we can get, we practically abolish the blue line and get the violet lines alone. Now we have simply produced these effects by varying the temperature, and this diagram enables me to point out one of the things to which reference will have to be made subsequently. The thicknesses of the calcium lines in the spectrum of the sun are also given. The two lines in the violet are really H and K. The

[1] "Recherches sur le Spectre Solaire," pp. 38, 39.

other line—the all-important one at low temperatures—is feeble and unimportant. So that both on the solar evidence and on the evidence of all these spectra, whatever the explanation may be, there is the undoubted fact that fundamental changes of intensity in the lines are produced by some cause or other, and if Kirchhoff's statement about the matching of lines is true for one temperature it is false for all the others.

11. In my reference to stellar spectra I mentioned the word "fluted" spectrum. Before Kirchhoff had published his first paper two very eminent Germans—Plücker and Hittorf—were working at spectrum analysis at Bonn, and they found that in the case of a great many simple substances what are called fluted spectra were to be observed as well as line spectra.

The accompanying diagram (Fig. 29) of the fluted spectrum of iodine will show the difference between these fluted spectra and the line spectra, on which we have been exclusively occupied up to the present.

We observe that the chief novelty is an absolute rhythm in the spectrum; instead of lines irregularly distributed over the spectrum, we have groups which are beautifully rhythmic in their structure. The next diagram (Fig. 30) shows us the radiation spectrum of a particular molecular grouping of carbon vapour, that also is beautifully rhythmic; the rhythm of each of the elementary flutings exactly resembling that of the iodine.

These observations were among the first to suggest the idea that the same chemical element could have two completely distinct spectra. They were eminently suggestive, for if two, why not many?

In my reference to the "long and short" method of observation I stated that it enabled us to note what happens when a known compound body is decomposed. With ordinary compounds, such as chloride of calcium and so on, one can watch the precise moment at which the compound is broken up—when the calcium begins to come out; and we can then determine the relative amount of dissociation by the number and thickness of the lines of calcium which are produced. Similarly with regard to these flutings we can take iodine vapour, which gives us this fluted spectrum, and we can then increase the temperature suddenly, so that we no longer get the fluted spectrum at all, or we may increase it so gently that the lines of iodine come out one by one in exactly the same way that the lines of calcium came out from the chloride of calcium. We end by destroying the compound of calcium in the one case, and by destroying the fluted spectrum in the other, leaving, as the result in both cases, the bright lines of the constituents—in the one case calcium and chlorine; in the other case iodine itself. I have by no means exhausted the list of difficulties which were gradually presented to us when we considered that both in the sun and in our laboratories spectrum analysis brought before us the results of unique, absolutely similar "chemical atoms." Not only were there differences, but the differences worked in different ways, whether we passed from low to high temperatures in laboratory work, or from the general spectrum or the flame spectrum in the sun.

But I have said enough for my present purpose; details on the points I have referred to and on others must be gone into afterwards.

How then was one to attempt to grapple with these difficulties? Was it the time to found new theories? or to rest and be thankful? Was it not better to appeal to what was known—to proceed in accordance with Newton's laws of philosophising, and start no new principle unless one were absolutely bound to do so: to appeal in fact to the law of continuity, and to suppose that the explanation of a very large part at all events, of this new matter, lay in the fact that, all unconsciously, spectroscopists had been working under more transcendental conditions as regards temperature than had ever been employed before, and that the natural result was that this higher temperature had done for the matter on which they had experimented exactly what all lower temperatures had been found to do. That is to say, that they had been broken up. In other words, it lent great probability to the view that when we subjected, say iron—because it is a good thing to keep to one specific substance—to one of these transcendental temperatures, we were no longer dealing with the spectrum of iron, but with the spectrum of the constituents of iron revealed to us by a temperature at which no experiments had been made before.

And one was the more struck by the probability of this being at all events an approximation to the truth by those stellar spectra to which I have referred, and by the knowledge we possessed, that in the case of a star of the simplest spectrum we were dealing with the highest possible temperature. So the idea was thrown out that these stars were really simpler in their structure; that their immense temperature had not allowed a complex evolution of higher complex forms of chemical matter to take place; and that we had there the primordial germs of matter, so to speak, or at all events something nearer to the beginning of things than anything that we had in this cool planet of ours, or anything that we were likely to find easily here, in consequence of the various difficulties which harass every kind of experimentation. It was imagined that we might picture to ourselves a sort of celestial dissociation in the heavenly bodies which would place those stars, the spectra of which have been seen, in a different order; that the first star with lines should be a star of the simplest spectrum, the next star with lines should be that which mostly resembled our sun, and that the last in order should be that one in which the lined spectrum had utterly disappeared in favour of the fluted spectrum. If this were granted for the stars, why not attach all this to the sun? Because, as has already been mentioned, all these lines which were seen in the spectra of the hottest stars were precisely those lines which were seen most intense in the hottest parts of the sun; and it did really seem as if in that way we could eventually sooner or later—most likely later, for Art is very long—get some light on the subject.

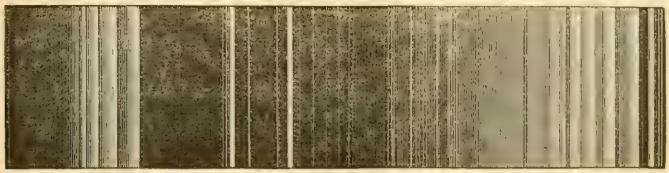
I at once say that this idea which was thrown out in the year 1873 on spectroscopic evidence had been anticipated by the foremost philosopher amongst English chemists of his time; I mean the late Sir Benjamin Brodie.[1] From considerations of a perfectly different kind he had come to the conclusion that our chemical philosophy was not anything like so firmly based as was generally imagined, and that, given a higher temperature, the elementary bodies would cease to be elementary—that the adjective "elementary" applied to them was merely the measure of our inability to dissociate them; and to watch the progress of dissociation when we got them at a temperature at our command. By a stroke of genius he, before anything was known about the chemistry of the sun, went to the sun for that transcendental temperature he was in search of; thus showing that he had an absolutely pure and accurate conception of the whole thing as I believe it to be—but that is anticipating matters. He suggested that the constituents of our elementary bodies might be found in the hottest parts of the solar atmosphere existing as independent forms. The whole merit of that conception therefore is due to Sir Benjamin Brodie, and dates from the year 1867.

Now we can easily understand, seeing that much of the spectroscopic work which had been done up to 1874 had had for its object the connecting—intermingling, so to speak—of solar, stellar, and terrestrial chemistry, that it was not a pleasant thing to find that the path seemed about to be such a very rugged one—that we seemed after all not to be in the light, but in the dark, and the very practical question was, what was to be done? Would it have been wise to have considered, *then*, the whole question of the dissociation of elementary bodies? I think it would not have been wise; the data were insufficient. The true thing to be done was, I think, to endeavour to accumulate a vast number of new facts and then to see what would happen when a sufficiently long base of facts had been obtained. What did we want? We chiefly wanted to settle those questions of the variations of spectra seen in our laboratories, and the variations observed when we passed from the spectrum, say of iron on the earth, to the spectrum of iron in solar spots and storms. The coincidence of lines of different bodies which had been referred to by Ångström and Kirchhoff also required investigation. What more ready means of doing that—what more perfect means were there than those placed at our disposal by photography? Photography has no personal equation, it has no inducement to cook a result either in one direction or the other, and it moreover has this excellent thing about it, that the results can be multiplied a thousandfold and can be recorded in an absolutely easy and safe manner. There were other reasons why photography should be introduced. We see at once that it it was quite easy to introduce the process of purification of the spectra to which I have already drawn attention, by merely comparing a series of photographs; the A, B, C of my diagram (Fig. 26) being represented, say, by iron, cobalt, and nickel, or any other substances. Again, it was quite possible by the use of the electric lamp to very considerably increase the

[1] "Ideal Chemistry." Lecture delivered to the Chemical Society in 1867, republished 1880. (Macmillan).

dispersion which Angström had employed; so that, if impurities had been suggested, there was now a method which has not yet been challenged of getting rid of them. If the dispersion was then insufficient there was nothing to prevent it being made very much more considerable, because a perfect photograph will bear a very considerable amount of magnification.

The diagram (Fig. 31) will show the method of photography that was adopted in this work, and by which the various photographs thrown on the screen were taken. The object was to compare the light of the sun with the light of the vapour in the electric arc of any particular substance that we wished to observe. By means of a heliostat and lens an image of the sun was thrown exactly between the poles of an electric lamp, and the rays diverging from it were collected by a second lens and again brought to a focus, this time on the slit of the spectroscope. The slit was provided with two slides, by means of which either its upper or lower half could be exposed, while the other half was covered. If we wished to take the solar spectrum first, the



Ultra-violet fluting. Blue fluting.

FIG. 30.—Carbon flutings, contrasted with the line-spectra of calcium, iron, aluminium, and other impurities of the poles.

poles were separated so that they might not obstruct the sunlight; the image of the sun was allowed to fall on one-half of the slit, and the plate was exposed. That half of the slit was then covered up and the other half opened (the sunlight being cut off), and the substance volatilised in the electric arc so that its image fell on the open part of the slit. The plate was again exposed, and so the two spectra were obtained, one above the other. In this way then we had, first of all, a spectrum of the sun compared with the spectrum of the particular substance we wished to map.

After that we had the long and short lines in the same substance photographed on another plate. After that we had all the substances which might exist as impurities in the first substance—that is to say, all the chemical elements photographed with their lines—their long and short lines, in precisely the same manner; and finally we had a comparison of the substances we wished to photograph, say iron, with a spectrum of every other substance which might contain these impurities. It will be seen therefore that an enormous number of photographs had to be taken. As

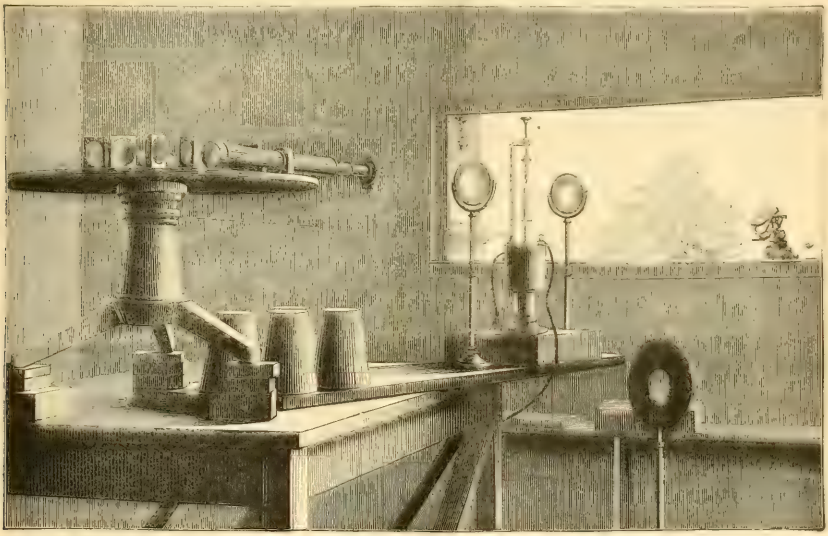


FIG. 31.—Arrangement for photographically determining the coincidence of solar and metallic lines.

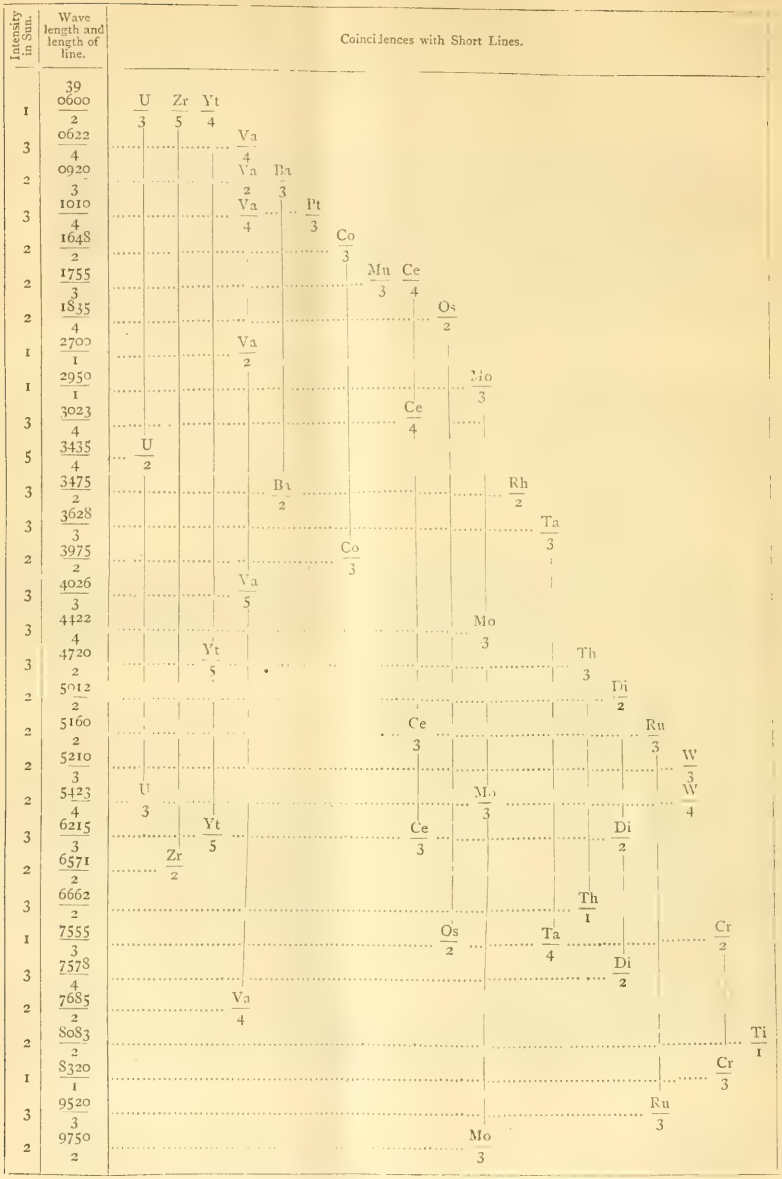
a matter of fact three or four thousand photographs have been taken, and a very considerable amount of time (about four years) was consumed in that way.

But it may be said, "Surely if you are going to limit yourself to photography, you will only be dealing with a very small part of the spectrum." My reply to that is that already in the year 1875, when a part of this work had been carried on, other laboratory work had given us reason to believe that what was then being done in photography at the blue end of the spectrum would be done by photography in every other portion, for in fact a spectroscopic study of the behaviour of bodies at low temperature, to which I hope I shall have time to refer, had led several to believe—at all events had led me to believe—that what one got in the text-books about actinism and so on was but a very rough approximation to the truth. We had been taking as the functions of light what were really the functions of the



bodies which received it, and it was therefore quite easy to imagine, and one was justified in hoping that as the work went on we should find, that what one particular kind of substance would do for the blue rays another particular kind of substance would do for the red rays and for the green rays, and so on. Capt. Abney in his lectures will show you that the spectro-

scope was no bad guide in that matter, and, thanks to his valuable researches, we are now able to photograph as well, if not better, at the extreme red end of the spectrum than we did at that time—years ago now—in the blue.

Well, then, four years were consumed in the accumulation of these facts. I do not now intend to call attention to the whole of them, but I will take some instances, directing special attention to what happened with regard to the spectrum of iron. This[1] is the final map produced up to a certain point. We have first the solar spectrum; below this are mapped all the lines of iron observed on one of the photographs which we obtained, including of course all impurities; and then follow the spectra of manganese, cobalt, nickel, chromium, uranium, cerium, and so on through the whole story. When that work had been completed in that manner we had to get rid of the impurities by the process which I have already explained, and at last we got what is called a purified spectrum, in which, along the horizon labelled iron we had only those lines left which we could not by any application of the principle which has been explained be shown to be due to the admixture of any other substance whatever. What then was the total result? The accompanying table (p. 320) will show the sort of corner in which we found ourselves after all this work had been accomplished. It gives the list of the iron lines which, after making every allowance for the existence of impurities, were found to coincide with lines in other substances.

It will be seen, for instance, that the two short lines 390600 and 395423 coincided, the first with short lines in uranium, zirconium, and yttrium, the second with short lines in uranium, molybdenum, and tungsten. Similarly there are two short-line coincidences with zirconium, and no less than six with vanadium, and so on. The total gives the coincidence of the lines of all the elements under the conditions that I have drawn attention to. So that the sum total of this really very laborious inquiry with regard to iron was that in the region between 39 and 40, the region including H and K on that map, where, before the introduction of photography, scarcely any iron lines had been seen, and where only five solar lines I think had been mapped, photography gave us a total of nearly 300 lines in the solar spectrum, and it gave us sixty-two lines of iron.

Of those sixty-two lines of iron only eighteen went straight; by which I mean that the remainder had short-line coincidences with the lines of other substances. So that the idea first thrown out by Kirchhoff, Ångström, and Thalèn of the possibility of the coincidence of lines among the metallic elements was enormously intensified. It will be seen that the thing is absolutely reversed in the case of iron, and it might be the case also in other substances. The fact of a line not being coincident with a line in another substance was the exception, and not the rule. The ratio in the case of iron being as 44 to 18.

It is amusing in the light of recent criticisms to go back to the old observations and to see with what pertinacity for the first two years we stuck to the possibility that the solar line or the iron line we were dealing with was a double line, and then, after we had to give that idea up, as the coincidences became of three, four, five, and sixfold complexity, we came to the conclusion that we were dealing with a common impurity. That of course was a point we could not settle until we had gone through all the chemical elements which were known to us, and it was going through so many substances which took up so much time.

But there was another question which became striking, in this excessively minute anatomy of even a very small portion of the solar spectrum, for I should say that the small range of the spectrum represented here forms a portion of a map which, when completed, will be the sixteenth of a mile long, so that after all we were dealing with an excessively small portion of the total work which had to be done. Having there mapped that small region, where without photography it would have been difficult to see any lines at all, we got in almost twenty cases from one end to the other, instances in which there was absolutely no relationship at all between the brightness of the iron line on our photographs and the darkness of the corresponding solar line.

These were carefully noted as "anomalous reversals," a term we coined in the laboratory at the time, and which we still use, although the word anomalous always suggests a very large amount of ignorance.

In more ways than one, then, this work landed us in rather worse confusion than we were in before. What we had to face was

[1] This map is too large and detailed to reproduce here.

(1) the variation in intensity as we passed from earth to sun, a variation so great that in some cases terrestrial lines were missing in the sun, and in others feeble terrestrial lines were greatly interrupted; and (2) the coincidence of lines in several spectra. That is, here and there along the spectrum we found the lines massed as it were even if the coincidence was but apparent, and it really did

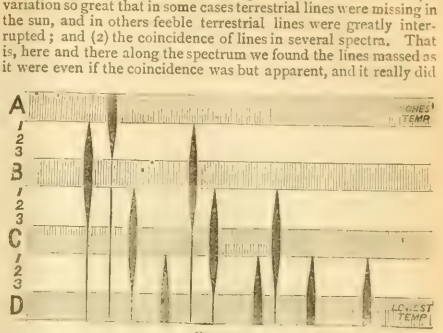


FIG. 31

seem time to consider what the effect would be, supposing that a dissociation was really going on under our eyes without our knowing or imagining anything about it. Why, it may be said, did you pitch on dissociation? For the reason that the startling results really after all contained nothing that was new—nothing that was novel about them the least in the world, if we regarded them with an absolutely unbiased and receptive mind. Dissociation would undoubtedly account for all the variations of intensity observed on passing from one temperature to another, as already exemplified in the case of the calcium lines, and moreover the short common lines, should they turn out to be truly common, which we were getting in the case of all substances, might be simply the equivalents of those short common lines of calcium which for years past we had watched coming out of the salts of calcium when decomposition was taking place. No new theory was necessary. The appeal to the law of continuity, as I said before, was really open to us, and it seemed to be our duty to appeal to it, and it was also easy to see, before really one has inquired into the matter, that if nature had built up the inorganic world in the way we now know she has built up the organic world, that precisely these facts and none other would be those she would present to us.

"Let us assume a series of furnaces A–D, of which A is the hottest (Fig. 32).

"Let us further assume that in A there exists a substance α, by itself competent to form a componnd body β by union with itself, or with something else when the temperature is lowered.

"Then we may imagine a furnace B in which this compound body exists alone. The spectrum of the compound β would be

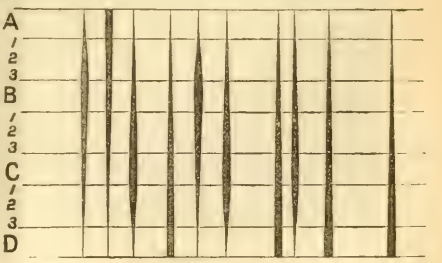

FIG. 33.

the only one visible in B, as the spectrum of the assumed elementary body α would be the only one visible in A.

"A lower temperature furnace C will provide us with a more compound substance γ, and the same considerations will hold good.

[1] The figures between the hypothetical spectra point to the gradual change in the interstices of the lines as the spectrum is observed near the temperature of each of the furnaces.

"Now if into the furnace A we throw some of this doubly-compounded body γ, we shall get at first an integration of the three spectra to which I have drawn attention; the lines of γ will first be thickest, then those of β; finally α will exist alone, and the spectrum will be reduced to one of the utmost simplicity.

"This is not the only conclusion to be drawn from these considerations. Although we have by hypothesis β, γ, and δ all higher, that is, more compound forms of α, and although the strong lines in the diagram may represent the true spectra of these substances in the furnaces B, C, and D, respectively, yet, in consequence of incomplete dissociation, the strong lines of β will be seen in furnace C, and the strong lines of γ will be seen in furnace D, *all as thin lines*. Thus, although in C we have no line which is not represented in D, the intensities of the lines in C and D are entirely changed.

"The same reasoning therefore which shows how variation in intensity can most naturally explain the short line coincidences—lines which I have termed basic, for the line of α strong in A is *basic* in B, C, and D, the lines of β strong in B are *basic* in C and D, and so on.

"I have prepared another diagram which represents the facts on the supposition that the furnace A, instead of having a temperature sufficient to dissociate β, γ, and δ into α, is far below that stage, although higher than B.

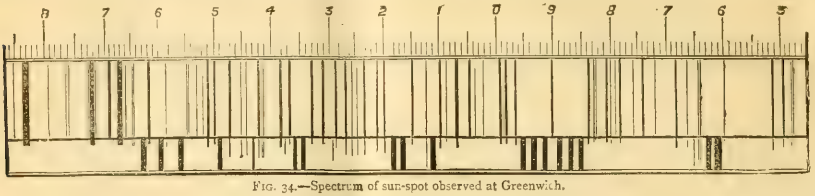

FIG. 34.—Spectrum of sun-spot observed at Greenwich.

"It will be seen from this diagram (Fig. 33) that then the only difference in the spectra of the bodies existing in the four furnaces would consist in the relative thicknesses of the lines. The spectrum of the substances as they exist in A would contain as many lines as would the spectrum of the substances as they exist in D; *each line would in turn be basic in the whole series of furnaces* instead of in one or two only."

We are therefore completely justified in asking whether these are not the differences in intensities of lines to which Kirchhoff and Ångström have referred, and it is quite easy to see that if we change the temperature of the furnaces in such a manner as to produce the strongest lines, owing to the greatest quantity of the vapour given off at any temperature, that the long lines produced at these different temperatures would vary, and the longest line produced in furnace D would not be the same therefore as the longest line produced in furnace A, so that in that way we can imagine a transcendental temperature giving a very long line to a particular substance, and that substance may exist highly compounded in another substance, and yet at a lower temperature it may only appear as an exceedingly short feeble line. The result of this reasoning was, in short, to explain at once variations of intensity of the short feeble lines which were common to so many of the so-called elementary bodies.

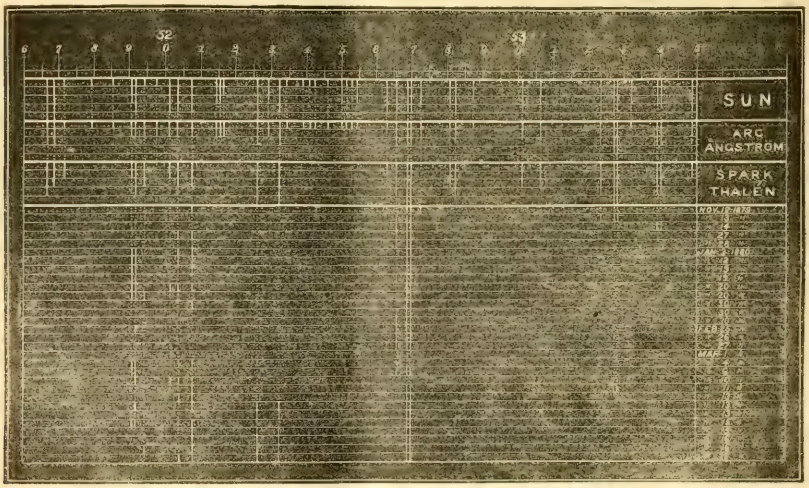

FIG. 35.—Portion of a large map showing the lines most affected in 100 sun-spots observed at South Kensington.

I am particularly anxious to point out that there is absolutely nothing new in these views. We have simply taken as our exemplar the behaviour of a known compound body, and then pushed the reasoning three or four stages further. We have gone just the safest possible way, by the easiest possible stages, from the known to the unknown.

I have now to refer, one by one, to the various tests which have been applied to these considerations, and I should now like to bring the first considerable test under notice. I shall show on a subsequent occasion the various laboratory methods that we possess of determining whether short lines are really the product of high temperature. I shall at once draw your attention to the fact that the short lines may be due, not merely to the work of high temperature, being thus truly produced by the temperature which we are employing, but they may be also the

indications of excessively complex groupings which are just dying at the temperature we are using at the time. So that if it may be permitted to coin terms I should like to call some of the short lines hot-short lines, and others cold-short lines. We shall see the reason by and by.

Now if this order of things is in any way as I have stated it, the first test that we have to employ is one of excessive simplicity. The differences between terrestrial and solar spectra indicate that if the view be correct differences should be seen in the spectra of the same substances observed in different parts of the sun.

We should now have a very distinct notion of the enormous difference of temperature between the highest and lowest reaches of the solar atmosphere. The lowest region of the solar atmosphere that we can get at must be far hotter than the highest part we can get at, at all events in times of eclipses; the lines that we should see therefore in the hottest region of the sun should bring us very near to the effects of this transcendental

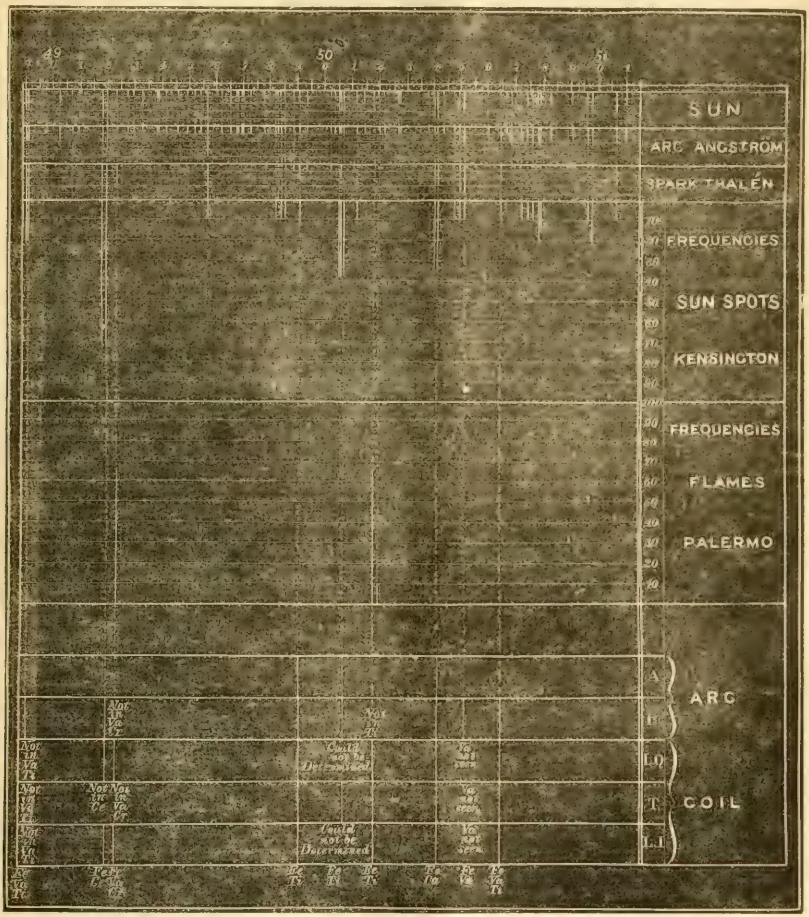

FIG. 36.

temperature to which I have referred, and the spectrum of iron seen in this way should bring us in presence of the result of the highest temperature.

Let us take then the storms as giving us the spectrum of the hottest part of the sun. Where are we to find the record of the coolest part? Now to get to this point we have had naturally to dismiss all the observations which have been made of the lines visible in solar prominences, of the lines thickened in solar spots and the like, because we know that in these prominences and spots we really are dealing with phenomena local to particular and highly heated regions.

Dealing with the whole solar spectrum we know that we are dealing with the whole of the solar atmosphere, however great, however high that atmosphere must be. Therefore we know that the solar atmospheric spectrum, the Fraunhofer spectrum, cannot by any possibility give us what is going on in any particular region—it must naturally be the summation of what is going on in every region where any absorption of any kind

whatever is visible. Therefore as the spectra of prominences and of storms may be stated to be the spectra of the hottest regions of the sun that we can get at in our inquiries. The lines in the solar spectrum affected neither in spots nor flames give us an approach to the cool spectrum we are in search of. We might expect if differences were observable that we should get something like this—

Lines special to prominences ... ... = hottest.
Lines special to spots ... ... = medium.
Lines affected neither in spots nor storms.. = coolest.

How have these views been tested. The first attempt made to get light out of this inquiry was one which simply dealt with a long catalogue of lines observed by Prof. Young in the memorable expedition of his to Mount Sherman, where, at the height of between 8000 and 9000 feet, with perfect weather and admirable instrumental appliances, about a month was employed in getting such a catalogue of lines as had never been got before. But it was found that, although the result of this inquiry was absolutely in harmony with these views, still after all one wanted more facts. Therefore we have endeavoured to get some of the facts here. And the way in which they have been collected is as follows:—During the last two years the spectra of 100 sun-spots have been observed in the observatory here—observed in a new fashion, and for a good reason I think. In this changeable climate it does not do to do as we began by doing—to attempt to observe all the lines acted upon in a solar spot. The excessive complication, and the intense variation of a spot-spectrum from the ordinary solar spectrum, cannot be better shown than by throwing on the screen the spectrum of one of the sun-spots lately observed at Greenwich.

The figure (Fig. 34) shows a limited part of the solar spectrum, and the lines thickened in the spot-spectrum. It will be seen therefore that to tabulate the existence and thickness and intensities of these lines over the whole of the solar spectrum would be a work which it would be difficult to accomplish in a single day, even if the day were absolutely fine. So that was given up in favour of a limited inquiry over a small part of the solar spectrum; limited further by this, that we only get the twelve lines most affected in each spot on each day. In this way we insure a considerable number of absolutely comparable observations, and we can more easily compare the spot results with those which had been obtained in the observation of the brightest lines in prominences, because when we begin to observe lines in the solar prominences one naturally begins by observing the brightest lines first. So that by observing the darkest lines first in the case of spots, one has a fairer comparison.

A diagram (Fig. 35) will show the result of our observations of 100 spots over a very limited part of the solar spectrum. We will begin by the individual observations. We have at the top the iron lines recorded among the Fraunhofer lines; below we have the iron lines recorded as iron lines by Ångström, who used an electric arc. Lower down we have the iron lines recorded by Thalèn, who used the electric spark. It will be seen that there is a very considerable difference in the spectrum of iron as viewed by means of the spark and by means of the arc, and that there is an equal difference between the spectrum of iron in the sun, that is to say, in the whole sun, determined by the Fraunhofer lines, and the spectrum of either the arc or the spark. It is also to be noted that the solar spectrum is more like the spectrum of the arc than the spectrum of the spark.

Since the relative intensities in all these cases are represented by the length of the lines, we have here an opportunity of observing and discussing the accuracy of Kirchhoff's statement that the iron lines in the sun correspond absolutely in intensity with the lines of iron seen in a light source here. It is necessary first of all to see which light source he fixes on, whether the arc or the spark. When this has been done it is found that the statement is really true with regard to neither.

That however is a digression; to proceed with the diagram, descending from this general spectrum of iron which we get by the absorption of the whole atmosphere of the sun independently of the hottest region and the coldest region—descending from the general to the particular—and taking that particular part of the solar atmosphere where the spots produce their phenomena, let us see what are the results in the case of the spots? We have in the vertical lines a record of the lines which are affected in each spot, and each of the spaces included between the horizontal lines represents a particular spot, the date being given on the right hand side; and these 100 lines which we have here represent the phenomena produced by 100 spots. The diagram is a small portion of the larger map. Now the wonderful thing that one is at once struck with is the absolute and complete irregularity of the whole result. There is no continuity among any of these lines. A careful inspection of the diagram shows us that, speaking in a general way, each of these lines is seen in one spot or another absolutely without the other. We have an *inversion* in the intensities of the lines when passing from spot to spot. Whenever we get a line intensified by Thalèn, we miss it in the spots, and, as a rule, what happens is that the spectrum of the spot is not only simpler than the spectrum of the arc, but simpler than the spectrum of the spark.

Now the importance of these statements depends on other statements which we can bring to confront with them. The next diagram shows the observations of 100 prominences observed between the years 1872 and 1876. (The diagram was thrown on the screen.) Prominences exist in a region of the solar atmosphere not very far from that occupied by the spots, but we have already seen that whereas the spots are produced by a downrush of cool material, prominences are produced by an uprush of hot material. Let us see therefore if any change is produced in the phenomena; whether we shall have exactly the same lines from the flames, or the prominences, as we have from the spots; whether we shall get the same information or no.

Here are the facts with respect to Tacchini's observations:—We begin as before with the whole absorption of the sun, Ångström's map, and Thalèn's map. I think you will see a very considerable change; the iron lines (for we are only dealing with iron) most prominent in the prominences are vastly different from the iron lines most thickened in the spots. The difference is shown in the annexed diagram (Fig. 36), which represents those individual observations both of spots and flames treated in a certain way with reference to the discussion. I will at once explain to you what that certain way is. We have, as before, the three data to begin with, and we have treated the sun-spot observations so that the lengths of the lines will represent the number of times they have been seen in 100 sun-spots; the line at wave-length 4919·5, for instance, has been seen seventy-two times; *that* line, in fact, has been seen more than any other; the one at 5005·0 some forty times, and so on; very many lines having been seen less than ten times. In another part of the same diagram we have summarised the individual results obtained from Tacchini's observation of prominences in exactly the same way. The line 5017·5 was seen in 66 prominences out of 100. But why I am particularly anxious to show this diagram is this, that it brings out the perfectly natural fact—for it is the natural fact—that over this region of the spectrum, at all events, no iron lines affected in the spots are visible in the prominences. If we assume that the region occupied by prominences is hotter than the region occupied by spots, that higher region ought to do this work, and it ought to be a work of simplification. Therefore I say it is a perfectly natural result, and not one to be wondered at, that in the spectra of the flames there is no line coincident with any of the lines seen frequently widened in the spots.

Now we have these three solar spectra here which we can compare one with the other. First of all we have the iron spectrum of the sun taken as a whole. Then we have next the spectrum of spots, which we know to be hotter than the sun taken as a whole. Then we have the spectrum of flames, which we know to be hotter than the spots. It will be seen that the story, as it runs from the top of the diagram downwards, is a story of greater simplicity, as it ought to be, and it was explained in the diagram which I exhibited before I began to show these results of absolute hard facts. It will be seen that the simplicity brought about by the reduction of lines actually seen as to number, is accompanied by the appearance of new lines (produced by the transcendental temperatures) in these regions. This first discussion of a large number of spectra and of spots, as compared with storms, is, I submit, in absolute harmony with the view of the dissociation of the elementary bodies by the solar temperature suggested by Sir Benjamin Brodie in 1867, and therefore I may further add that to me, at all events, it is absolutely inexplicable on any other view.

J. Norman Lockyer

(*To be continued.*)

INTERNATIONAL MEDICAL CONGRESS

THIS Congress, which opened by an informal reception at the College of Physicians on Tuesday, has so far been a real success. It has brought together something

like 2500 medical men, no less than 1000 being from abroad, and 500 from the provinces. Indeed, the attendance is more than double that of any previous Congress. Among the distinguished foreigners who attend the Congress are the following:—Dr. Fordyce Barker, New York; Dr. Billings, Washington; Dr. Bigelow, Boston; Professors Brown-Séquard, Paris; Chauveau, Lyons; Donders, Utrecht; Professors Holmgren, Upsala; His, Leipsic; Kölliker, Wurzburg; Klebs, Prague; Loven, Stockholm; Pasteur, Paris; Pflüger, Bonn; Panteleoni, Rome; Von Slawjansky, St. Petersburg; Stokvis, Amsterdam; Virchow, Berlin. A very large concourse of members thronged the rooms of the College on Tuesday, and crowded St. James's Hall yesterday morning, when Sir James Paget delivered the presidential address. The sectional meetings are being held in the rooms of the various scientific societies in the Burlington House region, and there are fifteen of them altogether. Prof. Virchow gave an address last night on "The Value of Pathological Experiments." To-day Prof. Maurice Raynaud gives a general address on "Scepticism in Medicine"; to-morrow Dr. Billings of Washington gives an address on "Our Medical Literature"; and to-morrow night the Lord Mayor and Corporation receive the members in the Guildhall at a *conversazione*. On Saturday there will be several excursions, and Sir Joseph Hooker will hold a reception at Kew in the afternoon. On Monday at a general meeting Prof. Volkmann of Halle will lecture on "Modern Surgery"; and on Tuesday Prof. Huxley will lecture on "The Connection of the Biological Sciences with Medicine." We this week give the opening address of Sir James Paget:—

As I look round this hall my admiration is moved not only by the number and total power of the minds which are here, but by their diversity, a diversity in which I believe they fairly represent the whole of those who are engaged in the cultivation of our science. For here are minds representing the distinctive characters of all the most gifted and most educated nations; characters still distinctly national, in spite of the constantly increasing intercourse of the nations. And from many of these nations we have both elder and younger men; thoughtful men and practical; men of fact and men of imagination; some confident, some sceptic; various, also, in education, in purpose and mode of study, in disposition, and in power. And scarcely less various are the places and all the circumstances in which those who are here have collected and have been using their knowledge. For I think that our calling is pre-eminent in its range of opportunities for scientific study. It is not only that the pure science of human life may match with the largest of the natural sciences in the complexity of its subject-matter; not only that the living human body is, in both its material and its indwelling forces, the most complex thing yet known, but that in our practical duties this most complex thing is presented to us in an almost infinite multiformity. For in practice we are occupied, not with a type and pattern of the human nature, but with all its varieties in all classes of men, of every age and every occupation, and all climates and all social states; we have to study men singly and in multitudes, in poverty and in wealth, in wise and unwise living, in health and all the varieties of disease; and we have to learn, or at least try to learn, the results of all these conditions of life while, in successive generations and in the mingling of families, they are heaped together, confused, and always changing. In every one of all these conditions man, in mind and body, must be studied by us; and every one of them offers some different problems for inquiry and solution. Wherever our duty or our scientific curiosity, or, in happy combination, both, may lead us, there are the materials and there the opportunities for separate original research.

Now, from these various opportunities of study, men are here in Congress. Surely, whatever a multitude and diversity of minds can in a few days do for the promotion of knowledge, may be done here.

But it is not proposed to leave the work of the Congress to what would seem like chances and disorder, good as the result might be; nor yet to the personal influences by which we may all be made fitter for work, though these may be very potent. In the stir and controversy of meetings such as we shall have, there cannot fail to be useful emulation; by the examples that will appear of success in research, many will be moved to more enthusiasm, many to more keen study of the truth; our range of work will be made wider, and we shall gain that greater interest in each other's views and that clearer apprehension of them which are always attained by personal acquaintance and by memories of association in pleasure as well as in work. But as it will not be left to chance, so neither will sentiment have to fulfil the chief duties of the Congress.

Following the good example of our predecessors, certain subjects have been selected which will be chiefly, though not exclusively, discussed, and the discussions are to be in the sections into which we shall soon divide.

Of these subjects it would not be for me to speak even if I were competent to do so; unless I may say that they are so numerous and complete that—together with the opening addresses of the Presidents of Sections—they leave me nothing but such generalities as may seem commonplace. They have been selected, after the custom of former meetings, from the most stirring and practical questions of the day; they are those which must occupy men's minds, and on which there is at this time most reason to expect progress, or even a just decision, from very wide discussion. They will be discussed by those most learned in them, and in many instances by those who have spent months or years in studying them, and who now offer their work for criticism and judgment.

I will only observe that the subjects selected in every section involve questions in the solution of which all the varieties of mind and knowledge of which I have spoken may find their use. For there are questions, not only on many subjects, but in all stages of progress towards settlement. In some the chief need seems to be the collection of facts well observed by many persons. I say by many, not only because many facts are wanted, but because in all difficult research it is well that each apparent fact should be observed by many; for things are not what they appear to each one mind. In that which each man believes that he observes, there is something of himself; and for certainty, even on matters of fact, we often need the agreement of many minds, that the personal element of each may be counteracted. And much more is this necessary in the consideration of the many questions which are to be decided by discussing the several values of admitted facts and of probabilities, and of the conclusions drawn from them. For, on questions such as these minds of all kinds may be well employed. Here there will be occasion even for those which are not unconditionally praiseworthy, such as those that habitually doubt, and those to whom the invention of arguments is more pleasing than the mere search for truth. Nay, we may be able to observe the utility even of error. We may not indeed wish for a prevalence of errors; they are not more desirable than are the crime and misery which evoke charity. And yet in a congress we may palliate them, for we may see how, as we may often read in history, errors, like doubts and contrary pleadings, serve to bring out the truth, to make it express itself in clearest terms and show its whole strength and value. Adversity is an excellent school for truth as well as for virtue.

But that which I would chiefly note, in relation to the great variety of minds which are here, is that it is characteristic of that mental pliancy and readiness for variation which is essential to all scientific progress, and which a great international congress may illustrate and promote. In all the subjects for discussion we look for the attainment of some novelty and change in knowledge or belief; and after every such change there must ensue a change in some of the conditions of thinking and of working. Now, for all these changes minds need to be pliant and quick to adjust themselves. For all progressive science there must be minds that are young whatever may be their age.

Just as the discovery of auscultation brought to us the necessity for a refined cultivation of the sense of hearing, which was before of only the same use in medicine as in the common business of life; or, as the employment of the numerical method in estimating the value of facts required that minds should be able to record and think in ways previously unused; or, as the acceptance of the doctrine of evolution has changed the course of thinking in whole departments of science: so is it, in less measure, in every less advance of knowledge. All such advances change the circumstances of the mental life, and minds that cannot or will not adjust themselves become less useful, or must at least modify their manner of utility. They may continue to

be the best defenders of what is true; they may strengthen and expand the truth, and may apply it in practice with all the advantages of experience; they may thus secure the possessions of science and use them well; but they will not increase them.

It is with minds as with living bodies. One of their chief powers is in their self-adjustment to the varying conditions in which they have to live. Generally those species are the strongest and most abiding that can thrive in the widest range of climate and of food. And of all the races of men they are the mightiest and most noble who are, or by self-adjustment can become, most fit for all the new conditions of existence in which by various changes they may be placed. These are they who prosper in great changes of their social state; who, in successive generations, grow stronger by the production of a population so various that some are fitted to each of all the conditions of material and mode of life which they can discover or invent. These are most prosperous in the highest civilisation; these whom nature adapts to the products of their own arts.

Or, among other groups, the mightiest are those who are strong alike on land and sea; who can explore and colonise, and in every climate can replenish the earth and subdue it; and this not by tenacity or mere robustness, but rather by pliancy and the production of varieties fit to abide and increase in all the various conditions of the world around.

Now it is by no distant analogy that we trace the likeness between these in their successful contests with the material conditions of life and those who are to succeed in the intellectual strife with the difficulties of science and of art. There must be minds which in variety may match with all the varieties of the subject-matters and minds which, at once or in swift succession, can be adjusted to all the increasing and changing modes of thought and work.

Such are the minds we need; or rather, such are the minds we have; and these in great meetings prove and augment their worth. Happily the natural increase in the variety of minds in all cultivated races is—whether as cause or as consequence—nearly proportionate to the increasing variety of knowledge. And it has become proverbial, and is nearly true in science and art, as it is in commerce and in national life, that, whatever work is to be done, men are found or soon produced who are exactly fit to do it.

But it need not be denied that, in the possession of this first and chiefest power for the increase of knowledge, there is a source of weakness. In works done by dissimilar and independent minds, dispersed in different fields of study, or only gathered into self-assorted groups, there is apt to be discord and great waste of power. There is therefore need that the workers should from time to time be brought to some consent and unity of purpose; that they should have opportunity for conference and mutual criticism, for mutual help and the tests of free discussion. This it is which, on the largest scale and most effectually, our Congress may achieve; not indeed by striving after a useless and happily impossible uniformity of mind or method, but by diminishing the lesser evil of waste and discord which is attached to the far greater good of diversity and independence. Now as in numbers and variety the Congress may represent the whole multitude of workers everywhere dispersed, so in its gathering and concord it may represent a common consent that, though we may be far apart and different, yet our work is and shall be essentially one; in all its parts mutually dependent, mutually helpful, in no part complete or self-sufficient. We may thus declare that as we who are many are met to be members of one body, so our work for science shall be one, though manifold; that as we, who are of many nations, will for a time forget our nationalities and will even repress our patriotism, unless for the promotion of a friendly rivalry, so will we in our work, whether here and now or everywhere and always, have one end and one design—the promotion of the whole science and whole art of healing.

It may seem to be a denial of this declaration of unity that, after this general meeting, we shall separate into sections more numerous than in any former Congress. Let me speak of these sections to defend them; for some maintain that, even in such a division of studies as these may encourage, there is a mischievous dispersion of forces. The science of medicine, which used to be praised as one and indivisible, is broken-up, they say, among specialists, who work in conflict rather than in concert, and with mutual distrust more than mutual help.

But let it be observed that the sections which we have instituted are only some of those which are already recognised in many countries, in separate societies, each of which has its own place and rules of self-government and its own literature. And the division has taken place naturally in the course of events which could not be hindered. For the partial separation of medicine, first from the other natural sciences, and now into sections of its own, has been due to the increase of knowledge being far greater than the increase of individual mental power.

I do not doubt that the average mental power constantly increases in the successive generations of all well-trained peoples; but it does not increase so fast as knowledge does, and thus in every science, as well as in our own, a small portion of the whole sum of knowledge has become as much as even a large mind can hold and duly cultivate. Many of us must, for practical life, have a fair acquaintance with many parts of our science, but none can hold it all; and for complete knowledge, or for research, or for safely thinking-out beyond what is known, no one can hope for success unless by limiting himself within the few divisions of the science for which, by nature or by education, he is best fitted. Thus, our division into sections is only an instance of that division of labour which, in every prosperous nation, we see in every field of active life and which is always justified by more work better done.

Moreover, it cannot be said that in any of our sections there is not enough for a full strong mind to do. If any one will doubt this let him try his own strength in the discussions of several of them.

In truth, the fault of specialism is not in narrowness, but in the shallowness and the belief in self-sufficiency with which it is apt to be associated. If the field of any specialty in science be narrow, it can be dug deeply. In science, as in mining, a very narrow shaft, if only it be carried deep enough, may reach the richest stores of wealth and find use for all the appliances of scientific art. Not in medicine alone, but in every department of knowledge, some of the grandest results of research and of learning, broad and deep, are to be found in monographs on subjects that, to the common mind, seemed small and trivial.

And study in a Congress such as this may be a useful remedy for self-sufficiency. Here every group may find a rare occasion, not only for an opportune assertion of the supreme excellence of its own range and mode of study, but for the observation of the work of every other. Each section may show that its own facts must be deemed sure, and that by them every suggestion from without must be tested; but each may learn to doubt every inference of its own which is not consistent with the facts or reasonable beliefs of others; each may observe how much there is in the knowledge of others which should be mingled with its own; and the sum of all may be the wholesome conviction of all, that we cannot justly estimate the value of a doctrine in one part of our science till it has been tried in many or in all.

We were taught this in our schools; and many of us have taught that all the parts of medical science are necessary to the education of the complete practitioner. In the independence of later life some of us seem too ready to believe that the parts we severally choose may be self-sufficient, and that what others are learning cannot much concern us. A fair study of the whole work of the Congress may convince us of the fallacy of this belief. We may see that the test of truth in every part must be in the patient and impartial trial of its adjustment with what is true in every other. All perfect organisations bear this test; all parts of the whole body of scientific truth should be tried by it.

Moreover, I would not, from a scientific point of view, admit any estimate of the comparative importance of the several divisions of our science, however widely they may differ in their present utilities. And this I would think right, not only because my office as president binds me to a strict impartiality and to the claim of freedom of research for all, but because we are very imperfect judges of the whole value of any knowledge, or even of single facts. For every fact in science, wherever gathered, has not only a present value, which we may be able to estimate, but a living and germinal power of which none can guess the issue.

It would be difficult to think of anything that seemed less likely to acquire practical utility than those researches of the few naturalists who, from Leeuwenhoeck to Ehrenberg, studied the most minute of living things, the Vibrionidæ. Men boasting themselves as practical might ask, "What good can come of it?" Time and scientific industry have answered, "This good: those researches have given a more true form to one of the most important practical doctrines of organic chemistry; they have introduced a great beneficial change in the most practical part of

surgery; they are leading to one as great in the practice of medicine; they concern the highest interests of agriculture, and their power is not yet exhausted.

And as practical men were, in this instance, incompetent judges of the value of scientific facts, so were men of science at fault when they missed the discovery of anæsthetics. Year after year the influences of laughing-gas and of ether were shown: the one fell to the level of the wonders displayed by itinerant lecturers, students made fun with the other; they were the merest practical men, men looking for nothing but what might be straightway useful, who made the great discovery which has borne fruit not only in the mitigation of suffering, but in a wide range of physiological science.

The history of science has many similar facts, and they may teach that any man will be both wise and dutiful if he will patiently and thoughtfully do the best he can in the field of work in which, whether by choice or chance, his lot is cast. There let him, at least, search for truth, reflect on it, and record it accurately; let him imitate that accuracy and completeness of which I think we may boast that we have, in the descriptions of the human body, the highest instance yet attained in any branch of knowledge. Truth so recorded cannot remain barren.

In thus speaking of the value of careful observation and records of facts, I seem to be in agreement with the officers of all the sections; for, without any intended consent, they have all proposed such subjects for discussion as can be decided only by well-directed facts and fair direct inductions from them. There are no questions on theories or mere doctrines. This, I am sure, may be ascribed, not to any disregard of the value of good reasoning or of reasonable hypotheses, but partly to the just belief that such things are ill-suited for discussion in large meetings, and partly to the fact that we have no great opponent schools, no great parties named after leaders or leading doctrines about which we are in the habit of disputing. In every section the discussions are to be on definite questions, which, even if they be associated with theory or general doctrines, may yet be soon brought to the test of fact; there is to be no use of doctrinal touchstones.

I am speaking of no science but our own. I do not doubt that in others there is advantage in dogma, or in the guidance of a central organising power, or in divisions and conflicting parties. But in the medical sciences I believe that the existence of parties founded on dominant theories has always been injurious; a sign of satisfaction with plausible errors, or with knowledge which was even for the time imperfect. Such parties used to exist, and the personal histories of their leaders are some of the most attractive parts of the history of medicine: but, although in some instances an enthusiasm for the master-mind may have stirred a few men to unusual industry, yet very soon the disciples seem to have been fascinated by the distinctive doctrine, content to bear its name, and to cease from active scientific work. The dominance of doctrine has promoted the habit of inference, and repressed that of careful observation and induction. It has encouraged that fallacy to which we are all too prone, that we have at length reached an elevated sure position on which we may rest, and only think and guide. In this way specialism in doctrine or in method of study has hindered the progress of science more than the specialism which has attached itself to the study of one organ or of one method of practice. This kind of specialism may enslave inferior minds: the specialism of doctrine can enchant into mere dreaming those that should be strong and alert in the work of free research.

I speak the more earnestly of this because it may be said, if our Congress be representative, as it surely is, may we not legislate? May we not declare some general doctrines which may be used as tests and as guides for future study? We had better not.

The best work of our International Congress is in the clearing and strengthening of the knowledge of realities; in bringing, year after year, all its force of numbers and varieties of minds to press forward the demonstration and diffusion of truth as nearly to completion as may from year to year be possible. Thus, chiefly, our Congress may maintain and invigorate the life of our science. And the progress of science must be as that of life. It sounds well to speak of the temple of science, and of building and crowning the edifice. But the body of science is not as any dead thing of human work, however beautiful; it is as something living, capable of development and a better growth in every part. For, as in all life the attainment of the highest condition is only possible through the timely passing-by of the less good, that it may be replaced by the better, so is it in science. As time passes, that which seemed true and was very good becomes relatively imperfect truth, and the truth more nearly perfect takes its place.

We may read the history of the progress of truth in science as a paleontology. Many things which, as we look far back, appear, like errors, monstrous and uncouth creatures, were, in their time, good and useful, as good as possible. They were the lower and less perfect forms of truth which, amid the floods and stifling atmospheres of error, still survived; and just as each successive condition of the organic world was necessary to the evolution of the next following higher state, so from these were slowly evolved the better forms of truth which we now hold.

This thought of the likeness between the progress of scientific truth and the history of organic life may give us all the better courage in a work which we cannot hope to complete, and in which we see continual, and sometimes disheartening, change. It is, at least, full of comfort to those of us who are growing old. We that can read in memory the history of half a century might look back with shame and deep regret at the imperfections of our early knowledge if we might not be sure that we held, and sometimes helped onward, the best things that were, in their time, possible, and that they were necessary steps to the better present, even as the present is to the still better future. Yes—to the far better future; for there is no course of nature more certain than is the upward progress of science. We may seem to move in circles, but they are the circles of a constantly ascending spiral; we may seem to sway from side to side, but it is only as on a steep ascent which must be climbed in zig-zag.

What may be the knowledge of the future none can guess. If we could conceive a limit to the total sum of mental power which will be possessed by future multitudes of well-instructed men, yet could we not conceive a limit to the discovery of the properties of materials which they will bend to their service. We may find the limit of the power of our unaided limbs and senses; but we cannot guess at a limit to the means by which they may be assisted, or to the invention of instruments which will become only a little more separate from our mental selves than are the outer sense-organs with which we are constructed.

In the certainty of this progress the great question for us is what shall we contribute to it? It will not be easy to match the recent past. The advance of medical knowledge within one's memory is amazing, whether reckoned in the wonders of the science not yet applied, or in practical results in the general lengthening of life, or, which is still better, in the prevention and decrease of pain and misery, and in the increase of working power. I cannot count or recount all that in this time has been done; and I suppose there are very few, if any, who can justly tell whether the progress of medicine has been equal to that of any other great branch of knowledge during the same time. I believe it has been; I know that the same rate of progress cannot be maintained without the constant and wise work of thousands of good intellects; and the mere maintenance of the same rate is not enough, for the rate of the progress of science should constantly increase. That in the last fifty years was at least twice as great as that in the previous fifty. What will it be in the next, or, for a more useful question, what shall we contribute to it?

I have no right to prescribe for more than this week. In this let us do heartily the proper work of the Congress, teaching, learning, discussing, looking for new lines for research, planning for mutual help, forming new friendships. It will be hard work if we will do it well; but we have not met for mere amusement or for recreation, though for that I hope you will find fair provision, and enjoy it the better for the work preceding it.

And when we part let us bear away with us, not only much more knowledge than we came with, but some of the lessons for our conduct in the future which we may learn in reflecting the work of our Congress.

In the number and intensity of the questions brought before us, we may see something of our responsibility. If we could gather into thought the amounts of misery or happiness, of helplessness or of power for work, which may depend on the answers to all the questions that will come before us, this might be a measure of our responsibility. But we cannot count it; let us imagine it; we cannot even in imagination exaggerate it. Let us bear it always in our mind, and remind ourselves that our responsibility will constantly increase. For, as men become in the best sense better educated, and the influence of scientific knowledge on their moral and social state

increases, so among all sciences there is none of which the influence, and therefore the responsibility, will increase more than ours, because none more intimately concerns man's happiness and working power.

But, more clearly in the recollections of the Congress, we may be reminded that in our science there may be, or, rather, there really is, a complete community of interest among men of all nations. On all the questions before us we can differ, discuss, dispute, and stand in earnest rivalry; but all consistently with friendship, all with readiness to wait patiently till more knowledge shall decide which is in the right. Let us resolutely hold to this when we are apart: let our internationality be a clear abiding sentiment, to be, as now, declared and celebrated at appointed times, but never to be forgotten; we may, perhaps, help to gain a new honour for science, if we thus suggest that in many more things, if they were as deeply and dispassionately studied, there might be found the same complete identity of international interests as in ours.

And then, let us always remind ourselves of the nobility of our calling. I dare to claim for it, that among all the sciences, ours, in the pursuit and use of truth, offers the most complete and constant union of those three qualities which have the greatest charm for pure and active minds—novelty, utility, and charity. These three, which are sometimes in so lamentable disunion, as in the attractions of novelty without either utility or charity, are in our researches so combined that, unless by force or wilful wrong, they hardly can be put asunder. And each of them is admirable in its kind. For in every search for truth we can not only exercise curiosity, and have the delight—the really elemental happiness—of watching the unveiling of a mystery, but, on the way to truth, if we look well round us, we shall see that we are passing wonders more than the eye or mind can fully apprehend. And as one of the perfections of nature is that in all her works wonder is harmonised with utility, so is it with our science. In every truth attained there is utility either at hand or among the certainties of the future. And this utility is not selfish: it is not in any degree correlative with money-making; it may generally be estimated in the welfare of others better than in our own. Some of us may indeed make money and grow rich; but many of those that minister even to the follies and vices of mankind can make much more money than we. In all things costly and vainglorious they would far surpass us if we would compete with them. We had better not compete where wealth is the highest evidence of success; we can compete with the world in the nobler ambition of being counted among the learned and the good who strive to make the future better and happier than the past. And to this we shall attain if we will remind ourselves that, as in every pursuit of knowledge there is the charm of novelty, and in every attainment of truth utility, so in every use of it there may be charity. I do not mean only the charity which is in hospitals or in the service of the poor, great as is the privilege of our calling in that we may be its chief ministers; but that wider charity which is practised in a constant sympathy and gentleness, in patience and self-devotion. And it is surely fair to hold that, as in every search for knowledge we may strengthen our intellectual power, so in every practical employment of it we may, if we will, improve our moral nature; we may obey the whole law of Christian love, we may illustrate the highest induction of scientific philanthropy.

Let us, then, resolve to devote ourselves to the promotion of the whole science, art, and charity of medicine. Let this resolve be to us as a vow of brotherhood; and may God held us in our work.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, July 25.—M. Wurtz in the chair.—The following papers were read:—On the comet *b* 1881, by M. Mouchez. The result of M. Oudemans' search among the Dutch Colonial Archives in South Africa is that the comet of 1881 is probably not that of 1807, but seen now for the first time.—Determination of the horizontal and lateral flexure and the flexure of the instrumental axis of the meridian circle of Bischoffsheim, by means of new apparatus, by MM. Lœwy and Perigaud.—On the equivalence of quadratic forms, by M. Jordan.—On chlorhydric ether of glycol, by M. Berthelot.—Anthracic vaccination; *résumé* of experiments made at Lambert, near Chartres, to test the method of M. Pasteur, by M. Bouley. The essence of the test consisted in inoculating vaccinated sheep with natural virus (anthracic blood from a sheep which died of the disease) instead of that prepared by processes of culture. The efficacy of the vaccination was fully demonstrated.—On the irreducible covariants of the binary quantic of the eighth order, by Prof. Sylvester.—Parabolic elements of the comet *b* 1881, by M. Bigourdan.—Observations of Schœberle's comet (*c* 1881) at Paris Observatory, by M. Bigourdan; also by MM. Henry.—Considerations on the forces of nature; inadmissibility of the hypothesis proposed by M. Faye to explain the tails of comets, by M. Picard. Whatever the nature of the repulsive force it can only be proportional to masses, not to surfaces, for *ideal* pressure on surfaces only arises from *effective* action on masses. No interposed matter can weaken or arrest its action, for the etherised medium penetrates all bodies. The action is propagated, not successively but instantaneously, being due not to an undulatory motion, but to shocks of etherised atoms and ponderable molecules, like gravitation; hence on a point in motion it is exerted in the same direction as the attraction exercised by the ponderable mass of the sun.—Remarks on the calculation of relative perturbations, according to M. Gylden's method, by M. Callandreau.—Hemihedral crystals with inclined faces as constant sources of electricity, by MM. Jacques and Pierre Curie. A plate suitably cut in such a crystal and placed between two sheets of tin forms a condenser which becomes charged when it is compressed. The authors give an absolute measure of the quantities of electricity liberated by tourmaline and quartz for a determinate pressure. It is shown how the instrument may serve in comparison of charges and capacities.—Determination of the angular distance of colours, by M. Rosenstiehl. He shows that three colours previously referred to, viz. orange, the third yellow-green, and the third blue, have the characters of a triad (that is, mixed in equal intensity, they produce the sensation of white). All the colours which occupy the angles of an inscribed equilateral triangle have the same properties.—Electric stopcock; transformation, transport, and use of energy, by M. Cabanellas.—On the heat of formation of explosives, by MM. Sarrau and Vieille. When an explosive is decomposed the heat liberated is equal (according to thermodynamics) to the excess of the heat of formation of the products over the heat of formation of the explosive. Hence, knowing, in a given case, the heat liberated by decomposition, and the composition of the products of the reaction, the heat of formation may be arrived at. The authors have applied the method to the principal explosives, and will shortly give the results.—Industry of magnesia (continued), by M. Schlœsing. He treats sewage matter with phosphate of magnesia, obtaining the phosphoric acid from natural phosphates of lime, and the magnesia from sea-water or water of salt marshes (it is precipitated by slaked lime). He produces a sort of vermicelli of lime, which gives a porous magnesia, on which the acid liquid acts easily.—On some reactions of morphine and its congeners, by M. Grimaux.—On a new process of vaccination of chicken cholera, by M. Toussaint. He inoculated fowls with blood of rabbits which had died of septicemia (or with matter cultivated from it), and the effects were those of an attenuated virus, which made the fowls refractory to cholera.—On a volcanic breccia capable of being utilised as an agricultural manure, by M. Carnot. The rock (from l'Herault) contains notable amounts of iron, lime, potash, and phosphoric acid.—Boric acid; its existence in salt lakes of the modern period, and in natural saline waters (second note), by M. Dieulafait.—On the extraordinary temperature of July, 1881, by M. Renou. It rose to 38°·4 on the 19th at the Park Observatory, a degree never experienced in Algiers, the Antilles, and Cayenne.

THURSDAY, AUGUST 11, 1881

VIVISECTION AND MEDICINE

THE International Medical Congress which has met in London during the past week is the largest that the world has ever seen. Medical men have assembled from every part of the earth, and their meetings seem to have been productive of general satisfaction. The objects of such a Congress are twofold—first, to tell or hear of new discoveries; and, second, to make men personally acquainted who have previously been known to each other only through their works. The latter is perhaps the more important of the two, for it is not only a source of very great pleasure, but of great profit, inasmuch as it enables men to form a juster appreciation of the workers in each department of medicine, and to avoid falling into the error, very common at the present day, of placing the observations and opinions of a mere tyro on a level with those of the scientific veteran. The work of the Congress has been divided into no less than fifteen sections, each of which has taken up some special department of the science or practice of medicine. For medicine is now not merely an art. It is no longer practised by simple rule-of-thumb. It is becoming, to some extent, a science, and exact knowledge is beginning to supplant blind empiricism. The means by which this change has been effected have been admirably illustrated in the addresses of Prof. Virchow, Mr. Simon, and Prof. Fraser.

They are those of experiment.

It is by experiment alone that we are able to distinguish between facts and fancies, between the ideas which arise in men's minds and the realities of the external world. It is in proportion as we bring our ideas into accordance with facts, or, in other words, as we *know* instead of *supposing*, that our power increases. Suppositions have been the *bête noire* of medicine. They have constantly misled men as to the causes, the nature, and the treatment of disease, and so long as they were not subjected to the test of experiment one supposition succeeded another, only to be itself replaced by a third, no less fanciful and no less delusive. This is the reason why the progress of medicine was formerly so slow, and it is only of recent years, since the experimental method has been employed, that medical knowledge has begun to acquire any exactitude. As Prof. Virchow points out in his address, the principle of modern medicine is localisation. We localise the causes and seats of a disease, we localise the action of remedies, and thus we are able to act with certainty so far as our knowledge will carry us. If we were able to localise certainly and define accurately the causes and seats of disease and the action of our remedies, we should possess a power to arrest or prevent disease which would render death by old age the usual, instead of as at present the exceptional, termination of human life. The experiments by which exact knowledge is obtained are, as Mr. Simon points out in his address, of two kinds. "On the one hand we have the carefully pre-arranged and comparatively few experiments which are done by us in our pathological laboratories, and for the most part on other animals than man; on the other hand, we have the experiments which accident does for us, and, above all, the incalculably large amount of crude experiment which is popularly done by man on man under our present ordinary conditions of social life, and which gives us its results for our interpretation." As an example of these two kinds of experiment, Mr. Simon quotes the classical experiments to which we habitually refer when we think of guarding against the danger of Asiatic cholera: "On the one side there are the well-known *scientific* infection experiments of Prof. Thiersch, and others following him, performed on a certain number of mice; on the other hand, there are the equally well-known *popular* experiments which, during our two cholera epidemics of 1848-49 and 1853-54, were performed on half a million of human beings, dwelling in the southern districts of London, by certain commercial companies which supplied those districts with water."

Popular experiments on the causes of disease are performed everywhere around us. Even when no epidemic prevails, our hospitals are crowded with the sick and dying, and many, very many, of these are dying from lack of knowledge. Probably the most dreaded scourge of this country is pulmonary consumption, or tubercle, as it is sometimes shortly termed, from a pathological product found in the lungs in this disease. This fearful malady seems often to attack the most beautiful and the most gifted. We have hospitals established especially for its treatment, and these institutions are crowded to the door, applicants having to wait weeks, perhaps months, before they can obtain admission. Hitherto we have been accustomed to regard this dreadful disease as one which we had no power to guard against, and whose attacks were no more to be averted than the stroke of a thunderbolt. But increased knowledge has already shown us how to avoid or prevent to a great extent the danger which we might otherwise incur from the lightning-flash, and increased knowledge is now showing us the causes which may induce consumption, and thus teaching us how to avoid them. By experiment upon animals we are learning the nature of the morbid processes which occur in this disease, and the conditions which give rise to them. We are learning that tuberculosis in cows may be communicated to healthy animals fed upon the milk which they yield, and that tubercular disease may also be induced by tubercular matter inhaled in the air or conveyed into the stomach. In these experiments upon animals we are simply repeating in a scientific way the popular experiments which men daily make in blind ignorance upon men. We communicate to a few animals a disease of which men perish by thousands, and by the sacrifice of a few dogs or rabbits we gain knowledge which may enable us to preserve the lives of thousands of men, and avert the anguish which their untimely death would cause to their relations.

In the out-patient departments of our general hospitals there are probably no cases more trying to the humane physician than the cases of consumption which he sees. Racked by cough and worn to a shadow as they often are, the physician knows that he can do but little for them if they are admitted. The utmost that his art is capable of is somewhat to alleviate their sufferings, and perhaps slightly to prolong a comparatively useless life. For these reasons he is often obliged to sacrifice his own feelings, and to refuse admission to the sufferer,

knowing that such an act of apparent charity would be real cruelty to others. By putting out of sight for a moment the fact that the number of beds in the hospitals is necessarily limited, and admitting such a consumptive patient, he would gratify his own feelings of kindness and benevolence, but would also exclude the young and strong who suffer from such acute diseases as inflammation of the heart, lungs, or kidneys, diseases which by proper care and attention in the hospital might, and very probably would, rapidly run a favourable course, and result in the patient's restoration to his family in health and strength, but which if left to themselves might damage the constitution of the sufferer and make him a burden on society, or quickly carry him off, leaving his wife a widow and his children fatherless. Although the wistful looks and earnest entreaties of the consumptive patient might lead some few morbidly sensitive and unreflecting persons to open the gate of the hospital to him rather than to the strongly-built and apathetic labourer whose life was in hourly peril from acute disease, yet most people would, in all probability, have little difficulty in deciding between the two cases, were they to apply for admission at the same time. But the case is different when the consumptive is refused, not because the other is already there, but because we know that in the ordinary course of events he must needs come. Here we are forced to disregard the promptings of sympathy with the case before us, and to do that which gives us present pain in order that we may achieve a higher though future good.

Now what occurs daily in the treatment of patients in hospitals, occurs also in the investigation of disease. In order to prevent the suffering, misery, and death of human beings, it is necessary that animals should be sacrificed, and that we should not allow ourselves, for the momentary gratification of those sentimental feelings which would lead us to avoid inflicting even slight and transitory pain upon animals, to neglect the acquirement of that knowledge which will be productive of lasting and widespread benefit to mankind. Many of those consumptive patients probably owe their weary days, their sleepless nights, and their shortened lives to popular experiments, experiments which have been made upon them just as they might have been made upon animals in the laboratory; but they have been made for a different purpose, for the purpose of gain—gain of money, and not of knowledge. These patients may have been supplied with milk from tubercular cows, because it was more profitable for the owners of the dairy to continue milking such animals than to destroy them. Such popular experiments may be carried on for many years without leading to any knowledge of their results, because the conditions under which their subjects live are so complex that it is very hard to ascertain which one of them is the cause of disease. And all this time the unfortunate sufferers from such experiments are suffering and dying for lack of the knowledge which might be acquired by a few experiments on animals in a laboratory. For in experiments in the laboratory the conditions are much more simple, and it is by such experiments on a small number of animals, instead of on an enormous number of human beings, that it has been ascertained that the milk of tuberculous animals is dangerous, and that the seeds of tubercle may be sown in the organism by its use. By similar experiments on a small number of animals in the laboratory we are now learning that many diseases are due to minute organisms, which we can cultivate at will under definite conditions, ascertaining their mode of growth and the influences which modify it. By such experiments M. Pasteur and others have found that these organisms may have their virulence so modified that they can be inoculated harmlessly, and that these inoculations will protect the animal against the virulent form, just as vaccination will protect against small-pox. It is only by an accurate knowledge of the causes of disease that we can hope to prevent its occurrence, and it is only by an accurate knowledge of its nature and seat, and of the action of drugs, that we can hope to cure it when it is present. The seat of disease may be determined without experiment upon animals, for, after the death of the patient, a post-mortem examination will show what parts of the body have been affected. But the alterations which we find in the dead body are only the results of disease. They are no more the disease itself than a field strewn with slain is a battle. As Prof. Virchow remarks in his address, disease presupposes life. In the dead body there is no disease; with death, life and disease disappear simultaneously. It is only in the living body that we can investigate the process of disease, and it is by experiments upon living animals that such exact knowledge of disease as we already possess has been acquired. Without the aid of experiment we are able to ascertain even less regarding the action of drugs than regarding disease, for the most powerful drugs will profoundly alter all the functions of life, and may, indeed, kill almost as rapidly as the lightning-flash, without leaving any visible trace behind to guide us to the seat of action. It is only by experiment upon living creatures that we can ascertain the action of a drug. Formerly, physicians were accustomed to make these experiments upon their patients, "pouring," as Voltaire has said, "drugs of which they knew little into bodies of which they knew less." Nor could they do otherwise. They were called upon to render assistance to their patients, and in their ignorance they did what they could; but instead of being guided by the lamp of knowledge, they followed the *ignis fatuus* of their own imaginations. As Prof. Fraser points out in his address before the Section of Pharmacology, fanciful resemblances between medicines and parts of the body, healthy or diseased, were supposed to show the organs which the medicines particularly affected, and the diseases in which they would be useful. For example, the white spots on the leaf of a plant were supposed to indicate that it would be useful in consumption, because in that disease white spots are found in the lungs. The carrot was employed in jaundice, because the plant and the patient were alike—yellow; and fruits were given in diseases of the heart or kidneys for no better reason than that they resembled these organs in shape. We now laugh at the wildness of these fancies, but we are justified in doing so only because they have been proved by experiment to be foolish. The experiments which proved this have mostly been made by giving drugs to large numbers of human beings, patient after patient being treated in the same way, until the inefficacy of the drug became so apparent that its use was finally abandoned. But while physicians

were thus blindly groping after the truth, their patients were suffering or dying. The doctors might *think*, perhaps, that some other treatment would have been more beneficial than the one they adopted, but they did not *know* it, and they were obliged to act according to the best of their belief. They were forced by the circumstances in which they were placed to perform what Mr. Simon terms a "popular" experiment instead of a scientific one, and the complicated conditions under which it was performed rendered it doubtful how much of the result was due to the drug and how much to the disease, so that a conclusion could only be arrived at after an immense number of trials. The method by which pharmacology is now studied is entirely different. Instead of first giving the medicine to a patient labouring under disease, the effect of any new drug is tested upon plants, such as algæ and fungi, and upon the lower animals, such as frogs and rabbits, and its mode of action is then exactly ascertained by means of experiment upon animals, so that before giving it to a human being we not only know what organs and structures in his body will be affected by it, but, to a great extent, *how* they will be affected, and consequently what changes will be produced in the course of the disease for which we administer it. Instead, therefore, of acting blindfold, we are able, almost with certainty, to relieve where we should formerly have been powerless, and to prevent suffering even when we cannot save life. The key-note of the present medical congress, struck by Prof. Virchow in his address, is the absolute necessity of experimentation upon living beings for the progress of medical science. Without experiment we can have no certain knowledge, and without knowledge we have no power to cure and prevent disease and death. Experiment there must be, and the only question is, Upon what living beings are the experiments to be performed, and how are they to be performed? Are they to be popular experiments, such as those to which Mr. Simon alludes, blindly made upon hundreds or thousands of human beings, healthy or diseased, or are they to be made upon a few animals in laboratories? The idea of inflicting pain upon animals is naturally repugnant to every well-regulated mind, and the thought that they are preventing unnecessary suffering is probably one of the greatest pleasures that tender-hearted and sensitive persons can experience. But this pleasure may be purchased too dearly, and by preventing the infliction of a certain amount of suffering upon a few animals a much greater amount of suffering may be caused to thousands of men.

Vivid pictures have been drawn of the suffering of animals in a physiological laboratory, and, misled by these, great numbers of people have been induced to join in the agitation, and consequent legislation, against vivisection, forgetting entirely that the pain inflicted in a vivisection experiment, except in the very rarest instances, is far exceeded, both in intensity and duration, by the sufferings of very many human beings in the course of a mortal disease, and of almost all animals except those slaughtered by man or killed and eaten by other animals. Every winter hundreds and thousands of birds and beasts die of cold and hunger, and hunger and thirst must almost always hasten the death of all wild animals. Sometimes they starve simply because no food is to be obtained; but the result is the same if weakness or disease renders them unable to reach it, although it may be plentiful around them. For while the death-beds of men are usually soothed by the kindness of the friends who moisten the parched lips and administer such nourishment as the sufferer can take, animals dying from old age, weakness, or disease have no such alleviations to their sufferings. The experiments of Chossat on starvation are generally quoted as the most cruel ever performed in a physiological laboratory, and yet they were only repetitions, on an exceedingly small scale, of the experiments which are constantly being performed by the conditions of life on thousands or millions of wild animals throughout the world. The animals on which Chossat experimented did not suffer more pain than those which die in the fields or forests because their death was witnessed by an observer who utilised it to gain knowledge of great importance to man, while the sufferings of their wild companions were unseen by any human eye. Yet many people seem to think that this is the case, and that the mere fact that pain is inflicted for a beneficial purpose renders it much less endurable than if it were simply inflicted thoughtlessly or in sport. More pain is caused by the whip of a London cab-driver in one day than is inflicted in any physiological laboratory in this country in the course of weeks; and the householder who puts down a pot of phosphorous paste to poison the rats which plague him inflicts upon them a more painful death than any they would be likely to suffer at the hands of a vivisectionist. Within the last few years those who experiment upon animals have been frequently and unjustly abused for their endeavours to gain the knowledge necessary to relieve pain and cure disease. They have, however, followed the example of their great master, Harvey, who held that to "return evil-speaking with evil-speaking" was "unworthy in a philosopher and searcher after truth," and have, like him, believed that they "would do better and more advisedly to meet so many indications of ill-breeding with the light of faithful and conclusive observation." They have, indeed, submitted to legislation which was felt to be unjust, inasmuch as it was directed against abuses which were not shown to exist, and which has already been found to hamper greatly the progress of experimental investigation in this country. Confident in their sense of the necessity for experiment, and feeling assured that ere long every one capable of forming a correct opinion and willing to take the trouble of ascertaining the facts for himself would perceive the necessity, they have remained silent, though assailed, like Harvey, with opprobrious epithets. Now, however, when the opponents of vivisection are exerting all their efforts to render legislation, already sufficiently oppressive, entirely prohibitory, the medical profession has spoken out, and with no uncertain voice, and has declared that experiments upon animals are absolutely necessary. Nor could medical men do otherwise. For no man can practise the medical profession without having occasionally to suffer most acutely on account of the imperfection of his knowledge. Often and often is his heart saddened by his patient's asking, with feeble voice and wistful eye, for the relief which he is powerless to give, and again and again has he to avert his face and to shake his head when, with agonised voices, the friends around the dying sufferer cry to him, "Oh, doctor, can nothing more

be done?" He sees his patients dying around him for lack of the knowledge which can only be obtained by experiment, and cannot but demand that the right to perform such experiments should be conceded to those who have qualified themselves for the task. There are those who say that, instead of trying experiments on the lower animals, medical men should experiment upon themselves; but, as Prof. Virchow points out, "Medical men are already more exposed in epidemics of all kinds in the performance of their duties in hospitals, in the country, in their nocturnal visits to the sick, in operations and necropsies, than any other class of the community as a rule; and it requires all the blindness of the animal fanatics to require also of them that they should test on their own bodies the remedial, or poisonous, or indifferent action of unknown substances, or that they should determine the limit of permissible doses by observations made on themselves." Nor is this all. Medical men do make experiments upon themselves, and some have sacrificed their own lives in such experiments. But such a method of observation is open to the objection that the sacrifice is to a great extent useless, as the death of the experimenter deprives him of the opportunity of recording the results of his experiment. Not only has the necessity for experimentation upon animals been clearly pointed out in the addresses delivered at the Congress, but this International Medical Congress itself, the greatest assembly of men qualified to judge in the matter that has ever been held, has expressed its judgment in the resolution passed, without a single dissentient, at its concluding general meeting:—

"That this Congress records its conviction that experiments on living animals have proved of the utmost service to medicine in the past, and are indispensable for its future progress; and accordingly, while strongly deprecating the infliction of unnecessary pain, it is of opinion that, alike in the interests of man and of animals, it is not desirable to restrict competent persons in the performance of such experiments."

THE BIBLE AND SCIENCE

The Bible and Science. By T. Lauder Brunton, M.D., D.Sc., F.R.S., &c. (London: Macmillan and Co., 1881.)

THIS work is in the form of seventeen lectures, which appear to have been delivered before an orthodox audience. Their scope is a wide one, ranging from sketches of ancient Egyptian and Israelitish life to the newest results in biological science. The principal object of the book is professedly that of showing how Darwinism is not antagonistic to Christian belief in general, or to the Mosaic account of creation in particular. But although this is the peg, so to speak, on which the course of lectures is made to hang, occasion is taken to devote the main part of the work to rendering in a plain and popular form an epitome of the leading facts of animal and vegetable morphology. This part of the work is admirably done. Indeed we do not know any writings of this nature better calculated to accomplish their object of making science easy to the general reader; and as the spirit is throughout tender, not to say sympathetic, towards traditional beliefs, the book deserves a large circulation among the always increasing class of persons who desire to learn, with a small amount of trouble and without fear of stumbling upon any cloven hoof, what biological science has done, is doing, and is likely to do. In a word, this part of the book, besides being written in a very graceful style, well exemplifies the truth that no writer is so able to serve up to the general public the facts of science in a palatable form as one who is himself a practical worker in the subjects which he expounds. In the interests of scientific education, therefore, we should like to see "The Bible and Science" pass through any number of editions.

Coming now to what is professedly the main object of the work, opinions of course will differ as to the success which has attended Dr. Brunton's efforts. And here it may be observed, first of all, that it is not very clear what the author himself thinks about the deeper topics that underlie his expositions. Apparently addressing an audience of the straitest sect, he judiciously steers clear of all topics save the one immediately before him, *i.e.* showing that the doctrine of evolution is not incompatible with that of the Mosaic cosmology; and although this is perhaps more effectively done than by many previous essayists, there is nothing to show that he is not adopting the method of St. Paul, which he commends, who "graduated his instructions to the people whom he was addressing, first giving them milk, and afterwards strong meat" (p. 358). Of course in this there is nothing to find fault. Because a man sticks to a text which does not happen to contain a confession of faith, we have no reason to object that he does not publish his religious opinions; only we think it well to point out that such is here the case, for any reader who is careless or obtuse might fail to perceive the adroitness with which Dr. Brunton steers his discussion among the rocks of dogma. At every point where we feel inclined to ask what our author himself believes, we virtually fall into a dialogue with him such as that with which is told of another eminent man—"What is your own creed?" "The creed of all sensible men." "And what is that?" "Sensible men never say."

But whatever Dr. Brunton's creed may be, his book everywhere breathes with such a genuine, and indeed we may say pathetic, appreciation of the beauty of the biblical writings and the nobility of religious belief, that if he fails to strike a chord which through all changes and chances is ever ready to vibrate deep down in the bass of human nature, we have only to commiserate the reader who has departed so far from the best and the purest of human emotions. Having travelled through Palestine, and knowing his Bible as thoroughly as his science, Dr. Brunton gives us some beautiful little sketches of Bible scenes, lighted up by numberless interesting suggestions derived from modern science, as well as by the glow of a singularly vivid imagination. Take, for instance, the following:—

"Never in my life do I remember a pleasanter moment than when I sat down on one of these, and looked at the scene before me, for this was the realisation of my childhood's dream; this was the spot where Joseph had lived. Yonder might have been the granaries where he received his brothers; here, in the neighbourhood, stood his house, where he returned, weary of his day's work, and was received by his lovely and loving wife Asenath,

whose gentle care had obliterated from his mind, not only all the sorrows and trials of his early life, the hatred of his brothers, his slavery in Egypt, his temptations in Potiphar's house, and his long imprisonment in the dungeon, but had almost made him forget his dead mother, the kind old father who had loved him so well, and the little brother Benjamin to whom he had been so deeply attached, so that he called the name of his first-born son Manasseh, 'For God,' said he, 'hath made me forget all my toil, and all my father's house.' . . . Let us, in order to form an idea of the country, suppose Joseph at this time of the year to be starting on a tour of inspection, and let us in thought accompany him.

"He has said farewell to his wife and children. His chariot and horses are at the gate, he springs up, and, accompanied by his attendants, drives onward towards the southern point of the Delta, just where it joins the Nile valley. At first he proceeds amongst shady trees, bounded on either side by fertile gardens; but as he rides on, his path lies through a strip of hard sandy desert, in crossing which the hind legs of one of the horses ridden by his attendants suddenly becomes paralysed, the animal sinks upon its haunches, and the horseman falls backwards. The Cerastes, or horned snake, a little viper only about a foot long, lying concealed in the sand, which it resembles in colour, irritated by the passage of the cavalcade, has bitten the horse's heel. Immediately the poison spreads up the leg, paralysing it, and, when it reaches the spinal cord, paralyses it also, thus destroying the power of both hind legs, and causing them to give way under the weight of the animal. Only within the last year or two have we learned the exact manner in which such a poison as this acts upon the body; but centuries ago its general effect was well known, and no more vivid description of it could be given than that of the dying Jacob, who compared his son Dan to 'an adder in the way, a serpent in the path, biting the horse's heels, so that the rider falleth backwards.'"

In a similarly picturesque manner we are carried through sundry scenes of early Egyptian life, of the bondage of the Israelites, their exodus, wanderings, and conquest of Palestine. In the course of this exposition, which only errs from being too short, several interesting suggestions are made as to the possible origin of the accounts of some of the Pentateuch miracles. Thus, speaking of the plagues, he says:—

"Amongst these was one that used to puzzle me not a little, the plague of 'darkness which might be felt.' Why, thought I, did all the people remain in the dwellings? Why could they not take lanterns with them and move out? But a day which I spent at Port Said showed me what was probably the reason. On waking in the morning it seemed to me that everything had been turned into pea-soup. Above, around, and on every side, was a thick yellow mist, darkening the air like a London fog, but differing from it in this respect, that it was a darkness perceptible; a darkness that might be felt, and painfully felt too, for it was caused by a storm of sand, driven by the wind, and every particle stinging the skin like a needle."

Again, regarding the passage of the Jordan, he writes:—

"One of the puzzles of my childhood's days was to imagine the condition of the waters thus cut off, for I fancied to myself the River Jordan like such streams as I had been accustomed to, flowing through a small channel with level meadows stretching on either side. How then, I thought, did the waters stand up as in a heap? I could picture to myself a steep, glassy wall of water running across the channel itself, but was there likewise a level wall along each bank, or did the waters flow over the meadows on either side? On seeing the Jordan, however, I at once discovered the solution of my childhood's difficulty."

Then, after describing the double channel of the river—

"Within this larger or outer channel, confined by its bank on either side, the waters of the river might become filled up as a heap. Here was an answer to one inquiry of childhood. There were no invisible or glassy walls, indeed, at the sides to prevent the waters from running over the surrounding country. Was there, then, one to draw them up in their channel, and thus to cut them off towards the Dead Sea? or was the dam here simply of earth? On standing at the river's brink, the whole scene appeared to pass before me. The country around is highly volcanic. Earthquakes occur with great frequency, and during such convulsions of nature we know that the relations of land and water become greatly altered. . . . Here, I thought, we have a method by which the Israelites were able to pass over dryshod. If the bed of the stream at this place underwent a sudden upheaval at the time of their passage, the consequences would be exactly those which are described in the Book of Joshua. The waters would rise up like a heap, filling the channel far up the valley, and those flowing down to the Dead Sea would be cut off.

"To some this explanation may seem mere fancy, but it appears to be the one accepted by the psalmist, for in the 114th Psalm we find, 'Jordan was driven back. The mountains skipped like rams, and the little hills like lambs. What ailed thee, O thou sea, that thou fleddest? thou Jordan, that thou wast driven back? Ye mountains, that ye skipped like rams; and ye little hills, like lambs? Tremble, thou earth, at the presence of the Lord, at the presence of the God of Jacob.' Here the psalmist seems to ask the question why Jordan was driven back, and to give us indirectly as an answer that the earth trembled, or, in other words, that there was an earthquake."

Dr. Brunton seems rather fond of this naturalistic or rationalistic method of explaining the miraculous element in the Old Testament records; but it is evident that the method only serves to let in miracles at the back-door instead of at the front. In this case, for instance, we cannot suppose Joshua to have known that an earthquake was about to take place, or, if he did, that its effect would be to divert the course of the river in the way that Dr. Brunton imagines. (There is a possibility, however, in the subsequent instance with which Dr. Brunton deals, of Joshua commanding the sun and moon to stand still, or become "dumb," that he expected an eclipse, and made good capital of his knowledge.) Therefore we must attribute the occurrence of the earthquake at the moment when the tribes were ready to pass over the river as due to a lucky coincidence which in itself would have been little short of miraculous. And the multiplication of such coincidences that would be required to explain all the Pentateuch miracles by this method would render their occurrence unaccountable save on the hypothesis of a designing mind; and this would constitute them miraculous in the sense of being supernatural. Moreover, many of the miracles cannot possibly be met even by the hypothesis of coincidence. Thus the passage through the Red Sea, which is so analogous to the passage through the Jordan, cannot be thus met. Here no earthquake could have produced the effect described, and if we accept the record as history we are compelled to "imagine the waters standing up as in a heap," with all the difficulty of "picturing a steep, glassy wall of

water," &c. We therefore question whether the theory which led, as Dr. Brunton tells us, to the "puzzles" of his "childhood's days," was really more beset with "difficulty" than the one whereby he now endeavours to make his "Bible" square with his "Science." Better swallow miracles in the lump, and so obtain at least consistency, than try to save the historical accuracy of the Pentateuch by playing hide-and-seek with scientific principles, with the result of always losing the game.

The closing chapters of the book are occupied with an endeavour to make evolution acceptable to the orthodox mind. Here we wonder that no mention is made of the circumstance that the order in which the flora and fauna are said by the Mosaic account to have appeared upon the earth corresponds with that which the theory of evolution requires and the evidence of geology proves. On the other hand there are some original ideas which may be found of use among Churchmen of Broad Church proclivities. Thus, after quoting Milton's account of Adam and Eve in Paradise, Dr. Brunton says :—

"This is a very beautiful picture, but it is not at all the one given in Genesis, for there we find that man, after the fall, was a being in the condition of savages of the Stone Age of Europe, clad in skins, and tilling the ground with implements of wood or stone, the use of metals being unknown till generations afterwards. And yet this being, low in the scale as we would term him, is represented as being so much higher in wisdom than Adam before the fall, that he was reckoned almost as a God in comparison, for in Genesis iii. 22, we read that 'The Lord said Behold! the man is become as one of us, to know good and evil.' So that while the Miltonic account of primitive man is an absolute contradiction of the notions of evolution, the Mosaic account is in conformity with them."

Obviously, enough allowance is not here made for what Mr. Darwin would call the "changed conditions of life" which befell Adam and Eve on being turned out of Paradise ; the curse so materially altered their "environment" that, as our other apostle of evolution would say, they were no longer "in harmony" with it. Surely, then, Milton was right in representing Adam and Eve in Paradise, not as worse than "savages of the Stone Age of Europe," but rather as a happy and innocent pair living in the midst of plenty, and having access to certain trees which presented physiological properties of so remarkable a character that we greatly wish Dr. Brunton, with his well-known ability in this line of inquiry, could find an opportunity of making them the subject of his next experimental research.

Less open to criticism is the following :—

"Now it is very remarkable that the doctrine of evolution, be it true or no, exactly agrees with the Mosaic account in reference to the place where man was created, whether this creation took place by special act or by evolutionary process. It took place in a paradise, where the air was balmy, where fruit-trees were plentiful, and where there were no carnivorous animals to prey upon and attack man. For man differs from the lower animals in the absence of a furry or hairy coat (although, curiously enough, such a coat is possessed by unborn children). Now, if for a moment we suppose ourselves driven to conclude that, in respect of his physical nature, man was evolved from a lower type of life, he could not have lost his hairy coat unless the air had been soft and balmy; for the essence of the doctrine is that the fittest only survive, and the fittest to survive exposure to heat or cold would not have been the naked, but the hairy individuals. Had not food been abundant and easily masticated, like the fruit of trees, man would not have lost the projecting muzzle and larger jaws of the apes, as a small jaw would be less fitted for the mastication of hard and innutritious food. Had man been liable to the attacks of wild beasts in this paradise, he could not have lost the large canines which form such powerful implements of defence in the gorilla. Nor would he have remained so long helpless, and unable to take care of himself, unless in such a paradise as we have supposed, where all the conditions of life were favourable. The children, which were long in developing, would have been at a disadvantage in the struggle for existence; they would have died off ; and the progenitors of the human race could never have developed into men.

"The site, too, of the paradise, according to the evolution theory, agrees exactly with that indicated in the Book of Genesis, and, indeed, until I saw a map by Haeckel, the most prominent defender of the evolution theory in Germany, I was puzzled to understand the Mosaic account. It reads thus [see Genesis]. The site thus indicated with the utmost precision by Moses is perhaps the only one upon the surface of the whole earth which fulfils the demands of the doctrine of evolution. For, as we have already seen, according to this doctrine man must have been developed in a genial climate, in a spot where abundance of food existed. Now such a place might perhaps be found in a similar latitude in America, but it is agreed by all evolutionists that man could not possibly have been developed in the new world, because his affinities are altogether with the monkeys of the old world, and not with those of the new. This is the only point, too, from which man could have spread in such a way as would agree with the distribution of races which we now find.

"But man did not always continue to live in this paradise. He was driven out; according to the theory of evolution, he was probably forced to migrate from this sacred spot for the same reason that races have been forced to migrate ever since, namely, want of food due to increasing numbers. These increasing numbers would, first of all, consume the natural fruits of the trees ; they would then be forced to till the ground, and, finally, some of them would be obliged to leave altogether. We read in Genesis that the woman was cursed in her conception being multiplied, and that the man was cursed by having to till the ground by the sweat of his brow. While in paradise he was naked, but after he left it he wore coats of skin. He had not yet learnt the use of metals, and his tools and implements must have been those of wood and stone. For, according to Genesis, it was not until several generations afterwards that Tubal-Cain taught men the use of brass and iron.

"However man was formed, then, the Mosaic account corresponds with what we find in the progress of civilisation—the Stone Age precedes that of Bronze and Iron. The paradise whose locality was indicated by Moses has now disappeared beneath the waters of the Indian Ocean. Whether its disappearance was preceded by some great volcanic eruption or not, and whether such an eruption is referred to in the mention of the flaming sword which turned every way, we cannot tell; but we have no indication in Genesis of the submergence of paradise until the time of the Flood, which," in accordance with Hugh Miller's idea, is supposed by our author to have been due to a subsidence of the land.

We have quoted this passage at length, because it serves to suggest that "the grand old legend" may contain in its beautiful allegory more of traditional history than the present age is always inclined to suppose. Enough has now been said to indicate the general nature of "The Bible and Science," although it may be added that it is fur-

nished with an excellent index. It is an entertaining and instructive book, and we wish it all success.

GEORGE J. ROMANES

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Thought-Reading

BY the courtesy of Dr. G. M. Beard of New York I had the opportunity of witnessing some interesting experiments in artificial trance performed on one of his trained patients, thought-reading being one of the phases exhibited. After his discovering objects in the usual way, I used a fine copper wire about a yard in length. I wound one end round the right hand of the patient (after he was hyperotised) and then placed his wired hand against his forehead. The patient then wandered round the room in an aimless sort of manner, the wire all the time being quite slack, but the moment I attempted, however gently, to increase the tension just sufficient for him to feel it, he instantly moved off along the direction of the wire, like a horse with a rein. I subsequently tried a thicker wire. The patient stood with his face in a direction at right angles to my own; he moved straight towards the table on my left hand, and after oscillating his head sideways as if trying to find some particular spot, he finally brought his forehead slowly but with great accuracy down upon a metal disk about 1½ inches in diameter, and at a distance of about 18 inches from the edge of the table. This was exactly what I had "willed."

The different effects produced by a slack and a stiff copper wire respectively would seem to show, clearly, that the patient cannot acquire the "will" of the operator unless the connection be sufficiently rigid to communicate the involuntary muscular action of the operator, however imperceptible such action may be to the latter himself, who wills what the patient is to do.

GEORGE HENSLOW

A Gun-Signal Recorder

IN the judgment recently delivered by Mr. Mansfield on the stranding of the steamer *Britannic*, he says:—"With respect to the signals from the Hook Tower it is stated that the gunner who discharged the gun—a twenty-four pound gun—commenced firing at 1.50 a.m. on July 4, and continued firing at intervals of ten minutes till 10.10 a.m. He took the time from his watch, as his sandglasses were unserviceable; he had no light but a dark lantern in his gunhouse. Without imputing to him intentional neglect of his duty or wilful misrepresentation, it seems to the Court that he may have been less vigilant and less accurate than men who were keenly awake to the difficulties of their position, and who must have known that the safety of the ship was involved in their taking the time between the signals with scrupulous care. In his unsupported testimony the Court cannot find that the signals from the Hook Tower were fired at regular intervals of ten minutes. Looking at the importance of accuracy between the intervals of the fog-signals, the Court wish to draw attention to the statement of the gunner that he has no relief in his duty, however prolonged it may be; nor do the Court find that there is any check, mechanical or otherwise, on the gunner to insure accurate firing."

The writer would suggest that a simple recording apparatus might be made by means of a clock controlling the movement of a strip of paper, as in the Morse telegraph; this strip being divided by transverse lines into spaces representing minutes and seconds.

A diaphragm of thin sheet iron, caoutchouc, or other suitable material, connected with a metal point as in the phonograph, would then register each explosion of the gun by depressing the point on to the paper strip, and either making a pencil-mark or a perforation. Such an instrument would be a check on the accurate firing of the gun in the station where it was placed, and the production of the strip would do much to remove the uncertainty which appears to have existed in the case above cited.

Liverpool, July 30 A. G. P.

Symbolical Logic

As Mr. Venn appears to be really serious in accusing me of having misquoted him, I may as well give the whole sentence which contains the statement which he says I distorted. The complete sentence is this:—

"Take, for instance, such problems as those of which Prof. Jevons has discussed a sample under the name of Numerical Logic (*Pr. of Science*, p. 169), as any of those which play so large a part in Mr. Macfarlane's volume, or, still more, as those problems in Probability which Boole justly regarded as the crowning triumph of his system."

I certainly thought that in this sentence the last relative pronoun *which* referred to Boole's probability problems in general, but especially to that much discussed problem (sometimes called his "challenge problem") which Boole gave in illustration of what he conceived to be the superiority of his "general method" over the usual methods. It never struck me therefore that Mr. Venn would seriously accuse me of misquoting him because (in order not to inflict upon the readers of NATURE the irrelevant three-quarters of the above sentence) I represented him as saying that Boole "justly regarded *his problems in probability* as the crowning triumph of his system." What then are the problems to which Mr. Venn refers? This, I own, is not a point upon which I have "any claim to call for an answer," but I think it is a point upon which he might courteously condescend to gratify the natural curiosity of many admiring readers of his "Symbolic Logic," who (unlike me, I am afraid) cannot be suspected of any unkind wish to place him in a difficulty.

Boulogne-sur-Mer, August 2 HUGH MCCOLL

Bisected Humble-Bees

AT the end of my garden two magnificent lime-trees grow, on which bees—of specimens of which I herewith send you portions—feed at this time of the year by hundreds—by thousands. What kind of bees are they? But the following are the points on which I should like some information. Every morning I find numbers of them on the ground, helpless, behaving very much like men when they are drunk. What causes this? Next, how comes it to pass that, apparently, these helpless bees all become bisected or trisected as the specimens I send? This morning there are hundreds of portions under the trees. We have a family of "fly-catchers" in the garden—would they do it?

T. MASHEDER

The Grammar School, Ashby-de-la-Zouch, July 29

[The bees are a common species of Bombus (Humble-bees), mostly workers, and mostly bisected at the junction of thorax and abdomen. Perhaps wasps are the culprits, adopting this method in order to rob the bees of their honey-bags. We shall be glad to have information on this point.—ED.]

A New Meter for Electric Currents

IN NATURE, vol. xxiv. pp. 294-5, you notice a new meter for electric currents, giving a description which is fairly correct for a slight sketch, and attributing the invention to Mr. Edison. The invention, however, is not American, but English, and, as the inventor, I think myself entitled to whatever credit this entirely novel system may merit. My patent rights for America have been purchased of me, and the invention will be shortly in use in New York.

JOHN T. SPRAGUE

Birmingham

[Our correspondent is doubtless right in his claim. Nevertheless the invention we referred to in the brief note in question has been recently patented in this country on behalf of Mr. Edison, presumably at a later date than our correspondent's invention. We should be glad if he would kindly furnish us with the date of his English patent. We certainly meant no injustice in publishing the note.—ED.]

A POPULAR ACCOUNT OF CHAMÆLEONS[1]

II.

THE next most interesting of the animal's life processes is its change of colour. Mistakes and exaggerations as to this matter are of very old date. Aristotle believed

[1] Lecture delivered at the Zoological Gardens on July 28, 1881, by St. George Mivart, F.R.S. Continued from p. 312.

the change to be due to the inflation of the body, and we all know that in Gay's fables it is represented as changing from black to green, blue, and white. The truth is the ground colour of the animal may vary from pale yellow to light or dark green, and so from a bluish to a dark leaden colour.

It is often of a general pale yellow tint, especially at night, in the dark and when perfectly dormant. The general colour need not be uniform, but in one region of one colour, and of another colour in another region, and yellow and bluish tints may be so mixed as to produce a green appearance. The colours may also be different on the two sides of the body. Its most ordinary colour resembles that of the bark of trees or that of leaves, but very distinct and very varied markings may appear as spots or stripes of pale gray, or brown, or black, or yellow, and the stripes or series of spots may extend longitudinally or transversely. Moreover the spots may be either close or distant, and round or angular. They may be dark on a light ground, or light on a dark ground. All the changes of colour which take place take place gradually, and the spots which appear, disappear, and re-appear, are not reproduced in the same places with the exception of markings which radiate from the eye, and others on the tail and limbs.

My poor friend, the late Mr. H. N. Turner, jun., remarked[1] of a chamæleon kept by him that its general tint varied from brown or olive to bright green and yellow. When brought from the dark into lamp-light he found that the side next the light changed sooner than the other. The line of prominent tubercles in the middle of the under surface of the body remains constantly white. Mr. Turner's experiments and those of van der Hoeven seem, as was to be expected, to negative the idea that the animal can assume the colour of surrounding objects.

This faculty of colour change is not really so exceptional a phenomenon as many persons suppose. It exists in certain mollusks, and notably in the cuttle-fishes, which rival the chamæleon in their changing tints. It is also found in certain frogs and lizards, especially in the American kind, called *Sphærops*. As to fishes, Dr. Günther tells us[2]: "In many bright-shining fishes—as mackerels, mullets—the colours appear to be brightest in the time intervening between the capture of the fish and its death, a phenomenon clearly due to the pressure of the convulsively-contracted muscles on the chromatophores. External irritation readily excites the chromatophores to expand—a fact unconsciously utilised by fishermen, who, by scaling the red mullet immediately before its death, produce the desired intensity of the red colour of the skin, without which the fish would not be saleable. In trout which are kept alive in dark places, the black chromatophores are expanded, and consequently such specimens are very dark-coloured; when removed to the light they become paler almost instantaneously.

The chamæleon lays eggs, and its manner of doing so has been described by Vallisnieri, who carefully observed the actions of a female in his possession. She wandered about on the floor of her inclosure till she found a place devoid of dust or sand. There she began to scratch, and continued scratching for two days, till she excavated a depression four inches wide and six inches deep, in which she deposited thirty eggs. She then carefully covered them up, first with earth, and then with dry leaves and twigs and bits of straw.

There are now fifty known species of chamæleon, and twenty-five of them are distinguished by prominences either on the end or sides of the muzzle, or over the eyes, or on the top of the head, or on the occiput. The first twenty-five of the entire list are devoid of such prominences. Their names and the localities whence they come are as follows:—

[1] *Proc.* Zool. Soc., 1851, p. 203.
[2] See his recent magnificent work on Fishes, p. 183.

(1) *Chamæleo vulgaris* is found in Southern Spain, Northern and Southern Africa, Asia Minor, Arabia, Hindostan, and Ceylon. No other kind of chamæleon has nearly so extensive a range.

(2) The kinds called *C. lævigatus* and (3) *C. affinis* both come from Egypt or Eastern Africa. *C. Senegalensis* (4), *C. gracilis* (5), *C. granulosus* (6), *C. dilepis* (7), *C. anchietæ* (8), and *C. fasciatus* (9), all come from Western Africa. *C. cristatus* (10) and *C. Burchelli* (11) come from Fernando Po. *C. capellis* (12), *C. ventralis* (13), *C. pumilus* (14), *C. namaquensis* (15), *C. melanocephalus* (16), *C. gutturalis* (17), and *C. tæniabronchus* (18), all come from Southern Africa. The kind called *C. tigris* (19) is from the Seychelle Islands; and the two species, *C. cephalolepis* (20) and *C. pollenii* (21), are from the Comoro Islands. *C. verrucosus* (22), with *C. balteatus* (23), *C. lateralis* (24), and *C. campani* (25), are from the great island called Madagascar.

As to each of the next list a word or two must be said.

The form called *C. antimena*[1] (26) is furnished with an outgrowth flattened from above downwards, at the end of the muzzle, which is cartilaginous towards its distal end. *C. Labordi*[2] (27) has a similar process more prolonged and entirely bony. *C. superciliaris*[3] (28) has a triangular prominence over each eye. *C. pardalis*[4] (29) has a nose dilated and toothed on each side in front. In *C. globifer*[5] (30) a globular prominence projects anteriorly from each side of the end of the muzzle. *C. calyptratus*[6] (31) and *C. calcaratus*[7] (32) have each the summit of the head conically produced. In *C. cucullatus*[8] (33) a very prominent flap extends out on each side from the occiput. In *C. gularis*[9] (34) there is also a pair of occipital flaps, and the same is the case in *C. brevicornis*[10] (35), with the addition of a process on the end of the snout, covered with smooth scales. *C. Malthe*[11] (36) has a pair of slightly different occipital flaps with the addition (in the male) of an obtuse nasal prominence, which is grooved above. *C. rhinoceratus*[12] (37) has a single central elongated bony nasal prominence, but no occipital flaps. In *C. minor*[13] (38) the male has two flat, compressed, diverging nasal prominences covered with large scutes. In *C. bifurcus*[14] (39) there is a similar pair of bony processes, and also in *C. Parsoni*[15] (40). In *C. O'Shaughnessi*[16] (41) there are also two divergent, compressed, scute-covered nasal prominences. In *C. gallus*[17] (42) the nose of the male is provided with a single long conical appendage, but it is flexible and covered with short tubercles. It and the preceding twenty species also all come from Madagascar. *C. nasutus*[18] (43), from Eastern Africa, has a similar flexible protuberance. The snout of *C. montium*[19] (44) has two prominences which are veritable nasal horns horizontally projecting forwards from above the nostrils. Each is encased in a finely-annulated sheath. It comes from the Camaroon Mountains. The male of *C. Owenii*[20] (45) has no less than three such sheathed horns, one projecting from the front of each orbit, and the other from the middle of the nose. It is an inhabitant of the Island of Fernando Po. In *C. Melleri*[21] (46) the male has a single, compressed bony prominence, sharp-edged above. It comes from Eastern Africa. *C. monachus*[22] (47) has two large occipital flaps. It is an inhabitant of

the Island of Socotra. There are also the occipital flaps in *C. Petersii*[1] (48), from Eastern Africa. The two remaining chamæleons are so distinct from the foregoing that they rank as a distinct genus called *Rhampholeon*, a genus which was instituted by Dr. Günther in 1874. The first of these, *R. spectrum*[2] (49) is from the Camaroons; the second, *R. Kerstenii*[3] (50) is from Eastern Africa. Both agree and remarkably differ from all other chamæleons in having the tail short, it being only one-third the total length, or even less. Though its end is prehensile, its prehensile action must be much less perfect than that of the tails of the preceding forty-eight kinds; but this defect is compensated for by the development of a sharp tooth, or denticle, at the inner side of the base of each claw, which must give it a firmer grip. Moreover in *R. spectrum*, though not in *R. Kerstenii*, the grip is yet further aided by a spine which projects vertically from the inner, or flexor, surface of each finger or toe. In *R. spectrum* each eyebrow is produced into a flexible horn-like prominence. In *R. Kerstenii* two long processes project forwards, one over and in front of either eye.

Thus the geographical distribution of the chamæleons is very remarkable. With the single exception of the common species they are entirely confined to Africa and certain more or less adjacent islands, and exist mainly on the south of the equator. No less than twenty-one out of the fifty kinds are from Madagascar, and of the twenty-five kinds which have been enumerated as having horns or other remarkable processes on the head, no less than seventeen are from the same very interesting island, which is thus the great home of chamæleons generally, and especially of these curiously distinguished kinds. The plate-snouted (*C. antimena* and *C. Labordi*), the bony, double-horned species (*C. minor*, *C. bifurcus*, *C. Parsonii*, and *C. O'Shaughnessii*), and the lofty-helmeted (*C. calyptratus* and *C. calcaratus*) kinds are quite peculiar to Madagascar. Those with occipital lobes are found not only there, but also in Mozambique and the Island of Socotra. The Madagascar single-horned *C. rhinoceratus* is resembled by the East African *C. Melleri* and the flexible-snouted Madagascar form, *C. gallus*, is resembled by the East African *C. nasutus*. The species with true horny sheaths to their horns (*C. montium* and *C. Owenii*) are exclusively West African forms.

Fernando Po possesses three species. Two are from the Camaroons. One is an inhabitant of the Seychelle Islands, and two are from the Comoro Islands between Africa and Madagascar. Apart from the common species three kinds are from Eastern Africa, two from Egypt and Abyssinia, nine from Western Africa, and eight from Southern Africa.

Such are the leading facts with respect to chamæleons considered by themselves. Let us now consider their more significant relations to other animals.

The entire mass of animals of all kinds, from what is commonly called the animal kingdom, in contrast with and in distinction from the vegetable kingdom: this great whole is divided into certain vast groups called sub-kingdoms, and the highest of them, called the vertebrate sub-kingdom (because its members possess a spinal column), comprises ourselves, with all beasts, birds, reptiles, efts, frogs and toads, and fishes. We and beasts constitute what is called a class—the class *Mammalia*. Birds form another class—*Aves*. Reptiles (*i.e.* all tortoises, lizards, serpents, and crocodiles, with certain extinct kinds) together constitute the class *Reptilia*. The efts of all kinds, with all frogs and toads, and some other creatures, living and extinct, form the class *Batrachia*, while all fishes are grouped together in the one class *Pisces*. But these five classes are not equally distinct one from another. Birds and reptiles, batrachians and fishes go together as two sets of classes or provinces. On the province containing birds and reptiles the name *Sauropsida* has been bestowed, while the term *Ichthyopsida* has been used to denote the province which contains both Batrachians and Fishes.

The existing class of reptiles contains four orders:—(1) *Crocodilia* (crocodiles and alligators); (2) *Lacertilia* (lizards); (3) *Ophidia* (serpents); and (4) *Chelonia* (tortoises and turtles).

The order *Lacertilia* is made up of a certain number of large groups, each of which is called a family, which family is again composed of genera, while each genus consists of one, two, few or many species.

The chamæleons, as we have seen, form fifty species arranged in two genera: forty-eight species in the genus *Chamæleo*, and two in the genus *Rampholeon*. These two genera together constitute a family—a family of the order Lacertilia.

Putting aside on this occasion a certain very exceptional genus called *Hatteria*, the families of the order Lacertilia may be enumerated as follows:—the true lizards (*Lacertidæ*); the Scinques (*Scincidæ*); the Chalcidians (*Chalcidæ*); the Iguanians (*Iguanidæ*); the Geckos (*Geckotidæ*); and the Monitors (*Varanidæ*).

From all these families that of the chamæleon differs most widely. It differs from all of these:—(1) in the compressed body raised from the ground by its long limbs; (2) in its tongue; (3) in its eyes; (4) in the shape of its feet; and (5) by the form of the tail. It further differs from the Iguanians, Lacertians, Scincs, and Chalcidians, in that its body is not covered with scales.

There are certain Iguanians which present a slight resemblance to the chamæleons: such are the American *Polychrus*, and still more *Sphærops*, which has the eye covered with a granular eyelid with only a small central aperture, and has an equal facility in changing colour. These, however, are but superficial agreements, and in all essential points *Sphærops* is a true Iguanian, and in no way a chamæleon.

Prof. Parker assures us that while the chamæleon is an animal, the structure of the skull of which is "specialised to the utmost," it is nevertheless in other respects a very low form.

The answer to our question, "What is a chamæleon?" is, then, that it is a very exceptional family of the order *Lacertilia*, an order of the class Reptilian, a class which, together with birds, form the Sauropsidian province of the great vertebrate sub-kingdom of animals.

Can we gain any light as to the mode of origin of chamæleons?

The best light we can obtain as to the origin of existing forms is derived from the fossil remains of creatures nearly allied to them. In this way we have been able pretty clearly to ascertain that hog-like creatures and ruminating animals are diverging offshoots from a much more ancient, common, and intermediate type.

In this way also we have, I think, fair evidence to show that the cats are derived from creatures more or less nearly allied to the existing civets.

But the science of organic fossil remains—palæontology—has only as yet been able (so far as I am aware) to point to one relic which has been supposed to be of chamæleon nature—part of a lower jaw from Eocene deposits in North America. It would be curious if an ancient chamæleon should be discovered to have inhabited a region so distant from the home of the existing kinds as is North America. It would not however be an unparalleled fact, for the existing Old World camel was once a New World form. The true nature however of the fragmentary fossil is very doubtful, and we may therefore say that as yet we have no evidence as to the antiquity of the family. But should the fossil turn out to be really part of the jaw of a chamæleon, it would but tend to show that the group itself existed already in Eocene times; it wou

[1] *P. Z. S.*, 1864, p. 470. [2] *P. Z. S.*, 1874, p. 443, Pl. LVII.
[3] Peters in von der Decken's "Reisen," iii. p 12, Table I. Fig 1; see also *Ann. and Mag. of Nat. Hist.*, September, 1880, p. 238.

not throw any light upon the *mode of origin* of that group.

The chamæleons have, as we have seen, their main home in Madagascar. That island is also the main home of another very exceptional group, the exceptional group of beasts called lemurs. But lemurs have much resemblance, though probably no true affinity, with apes, and the apes are a group, even more isolated perhaps than lemurs. It is as yet quite impossible to say from what root the ape order took its origin.

The same thing may be said (and a few weeks ago was said by our president in this room) respecting the cetaceans, the order, that is, of whales and porpoises. The same thing again may be said of that very exceptional order of flying beasts, the bats. The chamæleon family then is only one of many others which have this at present quite isolated character. But if we can obtain no clue as to the chamæleon's origin, can we detect any special or unexpected affinities between it and any other creatures which do not belong to its own class, the class of reptiles?

It is now very generally supposed that birds have been derived from reptiles, and there seem to have been two distinct lines of descent—the ostrich kind of birds, from extinct land reptiles called *Dinosauria* (of which the great *Iguanodon* of the Wealden formation is a type) and the other birds from extinct flying reptiles called *Pterosauria*, which had much analogy with our bats. This double origin (which I advocated ten years ago) has recently been reinforced by investigations of Prof. Vogt with respect to that extinct feathered creature of the Oolite, the *Archeopteryx*, which turns out to have many affinities with the Pterosauria.

Now the chamæleon has no resemblance either to the Dinosaurian or to the Pterosaurian reptiles, and certainly nothing could well be less bird-like in appearance or in habits than the chamæleon. The one only point of resemblance—that between its pincer-like feet and those of the parrots—is but a very incomplete one, as we have already seen. Nevertheless there is one strange and unexpected structural character already noted to which it may be interesting to revert.

In birds the lungs (unlike our own and those of beasts) are not closed bags, but communicate with air-sacs which extend far and wide within the body, and which doubtless facilitate their powers of aërial locomotion. In the most active lizards, which dart so quickly to their shelter that the eye cannot follow them, there is nothing of the kind; neither is there in those little lizards which take such long jumps with the help of their parachute-like wings, that they may be said to flit—lizards called by the absurdly formidable name of "flying dragons;" yet in the chamæleon, in spite of its sluggishness, such sacs are present, and thus render unavailing a character which might otherwise be employed to distinguish all birds from all existing reptiles.

But though neither comparative anatomy nor palæontology yet enables us to speculate profitably on the origin of the chamæleon's family, there is one feature met with in many of the species which tends to shed a certain amount of light on principles of variation, and therefore on that of specific origin generally. I refer to the circumstance that so many kinds of chamæleons develop crests, processes, or horns on the muzzle and over the eyes or on the occiput. These outgrowths are so different one from another that it is impossible to believe that they have arisen by inheritance and descent from any one peculiarity of the kind. Superciliary prominences could not give rise to nasal protuberances, or bony outgrowths to true horn-sheathed excrescences, and none of these could either be the parents or the offspring of occipital flaps.

The phenomenon is parallel to what we find in certain groups of birds, as *e.g.*, the birds of paradise, so many kinds of which develop unusual feathery outgrowths—these outgrowths being often so different in nature that they cannot be supposed to have been derived by inheritance one from another.

In such birds then we must admit (as I have long ago urged) that there exists an innate tendency to unusual outgrowths of feathers of one or another kind, and similarly we must admit that there is extant in the nature or essence of chamæleons a tendency to osseous or horny outgrowths from the head of one or of another kind. It has been suggested that these outgrowths in the males are due to the wayward fancy of female chamæleon taste. And certainly the female chamæleon, with her exceptional power of independently moving her eyes, and so simultaneously considering and accurately comparing the horns and warts of two rival swains, is unusually qualified for making a careful matrimonial choice. Seriously speaking, however, I regard this explanation as quite inadequate.

I have elsewhere[1] given my reasons for considering this explanation to be a mistaken one, but the question is far too wide to discuss to-day, suffice it to say that even if this hypothesis were correct it would but imply the presence of an innate tendency in the female to admire horny and warty prominences of certain varied kinds. The one innate tendency is as mysterious, and when deeply considered as significant as in the other.

But apart from these questions, which, however interesting they may be, are still matters of uncertain speculation, the actual structure and the unquestionable facts of the chamæleon's physiology are, as I trust you will now agree with me in saying, matters of very great interest. They offer fields as yet unexplored for careful observation and experiment. Even the most peculiar and important of all the chamæleon's actions—the emission and retraction of its tongue—are actions which, so far as I know, are not by any means clearly understood. But when to such matters of direct observation or immediate inference we add the problems to the solution of which elaborate reasoning has to be employed—reasoning based on wide knowledge of the structures of animals existing and extinct—it will, I think, be evident that the leisure of a long life might be usefully devoted to obtaining a complete and far-reaching knowledge of the natural history of that exceptional family of Lacertian reptiles, the family of the chamæleons.

THE INTERNATIONAL MEDICAL CONGRESS

THE seventh meeting of the International Medical Congress, which has just been held in London, has been remarkable from many points of view. The sudden growth of the Congress from an assembly of 600 to one of over 3000 members, the truly cosmopolitan character of the gathering, the great scientific activity displayed, the lavish private and public hospitality and marked Royal patronage conferred, have one and all marked out this meeting as a very great event. It has been the largest and most complete assembly of scientific men that this age, and therefore any age, has ever witnessed, and if the results to science should prove to be at all commensurate, it will be a very prominent event in the history of the progress of science.

The many and complicated arrangements have been admirably planned by Mr. MacCormac and his able assistant, Mr. Makins, and they have borne successfully the heavy strain of a larger number of members than was previously expected. The Congress has held six general meetings, at each of which an address has been delivered, and the more special work has been conducted in the fifteen sections among which it has been split up. Sir James Paget, as President, delivered the opening address on Wednesday last, which was characterised by his usual

[1] "Lessons from Nature," Chap. X. (Murray, 1876).

eloquence and scientific ability. He did not confine himself to any one subject, but glanced at the progressive character of science, the need for the work of all varieties of minds, and the aim and purpose of science as applied in the medical arts. On the same afternoon Prof. Virchow discussed the value of pathological experiment in an address displaying the most thorough grasp of his subject and vigour of thought and diction; he attacked the opponents of vivisection for their utter inconsistence, and gave a very weighty protest against their claim to regulate the pursuit of knowledge. The French address was to have been read by Prof. Raynaud of Paris, but his sudden death only a few days before the meeting prevented this arrangement being carried out, and the address he had already prepared was read by his friend, M. Féréol: it dealt with the subject of the right sphere of action, and the influence of scepticism in medicine. On Saturday Dr. Billings gave a masterly address on Medical Literature; his tables showed a most alarming growth in the production of volumes and periodicals during the past ten years, but he was able to give some consolation by the statement that the rate of growth had of late shown some slackening: his wise and witty remarks on book-writing, bibliography, cataloguing, and reference were especially valuable as coming from a man of considerable experience in these matters, and applying equally to all varieties of literature. On Monday, Prof. Volkmann, one of Mr. Lister's most ardent disciples in Germany, gave an address on Modern Surgery, which resolved itself into a review of the progress and results of antiseptic surgery. He was followed by Prof. Pasteur, who in a few moments described his latest experiments, and announced results which promise to have as important effects for useful animals as Jenner's vaccination has for man. The final general meeting was held on Tuesday last, when Prof. Huxley addressed the Congress on the Connection of the Biological Sciences with Medicine, tracing this connection from step to step, and pointing out the necessity for a similar close union in the future. The entertainments during the week have been many and brilliant, including, in addition to many partly private, a soirée at South Kensington Museum, a dinner at the Mansion House, reception at the Guildhall, reception by Earl and Lady Granville, *conversazione* at the College of Surgeons, and informal dinner at the Crystal Palace. Notwithstanding all these diversions the real hard work that has been done every day by the great mass of the members of the Congress has been very great, and this, and the free interchange of ideas in conversation of many workers in the same part of the field of science, must be productive of good, both by its direct effect and by the stimulus to work it must afford. Among the many subjects discussed, the germ theory and its various practical bearings and outcomes, have had a prominent share. In the Surgical section there was a debate on the treatment of wounds, in which it was incidentally raised, and there appeared to be a general consensus of opinion that particulate germs play an all-important part in the production of wound diseases, though there was by no means such agreement as to the best means of treating wounds. In the Pathological section a long and very animated discussion was introduced by Prof. Klebs, who discussed the relations of minute organisms to certain specific diseases. Dr. Charlton Bastian supported his well-known views, and was opposed by Lister, Virchow, Pasteur, Hueter, Cheyne, and Roberts, and it was made abundantly evident that the germ theory of disease has not only established itself firmly in the faith of scientific pathologists, but that its importance is becoming wider and greater with rapid strides. By far the most valuable of all the communications bearing upon this subject was M. Pasteur's account of his recent "vaccination" experiments. He has found that by a special mode of cultivation of the poison of chicken cholera he can obtain an attenuated or weakened virus, and that vaccination with this attenuated virus, which merely causes slight and transient local mischief, protects fowls completely from the most active virus for a certain time, and enables them to resist the disease for a far longer period. He has also demonstrated that the source of the attenuation of the virus is the action of atmospheric oxygen, for it is only when the "germs" are allowed to develop in the presence of abundance of oxygen that the containing fluid becomes less intensely poisonous. A "vaccine" for splenic fever or charbon could not be obtained in this manner, but if the virus be allowed to develop in a solution at a temperature of 42°—43° C., with free exposure to the air, it quickly becomes less active, and ultimately, at the end of a few weeks, dies. Experiments on sheep have shown that vaccination with this "attenuated lymph" protects the animal from the action of the purer and more active poison. But great as will be the value of these researches, even if only applied to the two diseases in question, it is far more important to notice their extreme importance from a scientific point of view. First of all they explain in part the action of oxygen in preventing septic infection, and the inflammatory complications of wounds. But they also excite the hope, and go far towards showing that it is not improbable, that by some special form of cultivation every disease-virus may be thus attenuated and a poison result, which if inoculated will produce only a transient local change, but will protect from the virulent form of the disease as completely as efficient vaccination protects from small-pox. Prof. Pasteur referred to the germ theory of disease as one which has ceased to number the practical triumphs it has won; and every day is giving results to add to its importance and value.

NOTES

Mr. W. H. Christie, F.R.S., has been appointed Astronomer Royal in succession to Sir George Airy, who retires after having filled the office for something like half-a-century.

On October 17 next, fifty years will have elapsed since Prof. Bunsen, the eminent chemist, received his doctor's diploma from Göttingen University. He, however, intends to absent himself from Heidelberg on the day in question, in order to avoid all congratulations and speech-making.

Mr. W. A. Forbes, B.A., Fellow of St. John's College, Cambridge, Prosector to the Zoological Society, has been appointed Lecturer on Comparative Anatomy at Charing Cross Hospital, *vice* the Rev. J. F. Blake, removed to Nottingham.

The discussion in connection with Mr. Mundella's able statement on the Education Estimates had no special bearing on the teaching of science in elementary schools. Steps are evidently being taken to make elementary education more and more efficient, to give those whose school years are short and precious every opportunity of acquiring a knowledge of things that will be really useful to them in after life. It is clear from the facts and figures, as well as the tone of Mr. Mundella's address, that the education of the country is safe in his hands. In the proposals for the revision of the Code laid on the table of the House are several changes for the better. In infant schools, for example, part of the course provided for is a systematic one of simple lessons on objects and on the phenomena of nature and common life. Among the "Class Subjects" in boys' and girls' schools are Physical Geography and Elementary Science, and among the specific subjects are Mechanics, Animal Physiology, Botany, Principles of Agriculture, and Domestic Economy. This is all in the right direction, and is just what we should expect from an Education Minister like Mr. Mundella.

Mr. Mundella stated on Monday that Prof. Leone Levi has prepared an elaborate report on technical education in Italy,

which will be referred to the Royal Commission about to be appointed.

At the Exhibition of Electricity the completion of the English telegraphic department is progressing favourably. The series of solid and compact sounders used in the British service will contrast, not without advantage, with the quadruplex Baudat and other apparatus presented by the French administration. The Italian historical section is full of relics of instruments used by Galvani, Volta, &c. A large number of autographs will be exhibited, among which we may note a letter from Volta to Sir Joseph Banks, then president of the Royal Society. This document is stated to be the first description of the Voltaic battery ever written by its inventor. A small magnet, which Galileo armed with his own hand, is exhibited, as well as another magnet used by the academicians "del Cimento" for their determination of the laws of the variation of the attractive power according to distance. The Academy of Aërostation of Paris exhibits a model of the electro-subtractor, an electrical balloon constructed according to the principles advocated by Dupuy de Lome, and a number of other electrical instruments. M. Jules Godard, a well-known aëronaut, has sent an electrical warner; when the balloon is descending an electrical vibrator is set in operation; when it is ascending another bell rings. This effect is obtained very simply by a valve, which is in equilibrium when the balloon keeps its level, and is moved by a slight wind. The formal opening was to take place yesterday by a visit of the President of the Republic, and the doors will be thrown open to the public to-day, although much remains to be done for the completion of the display, which will be a great success.

The French Government has appointed a Committee, presided over by Rear-Admiral Bourgeois, to study the different applications of electricity to navigation.

The rapid advance of civilisation, it is admitted, has the effect of causing native races more and more to disappear. It is therefore the duty of scientific ethnology to save the little which exists still in its originality from destruction, and to preserve the few authentic fragments of an epoch which threatens to be annihilated. The Anthropological Society of Hamburg has issued an application to all those who have occasion, either by their position or calling, &c., especially to consuls, missionaries, merchants, captains, to enter their notes on little-known countries and their populations on a schedule which the Society will supply. The questions being intentionally short and as few as possible, any further communications on the character of the country, notes on the climate, corrections of the charts and sailing directions, would be thankfully welcomed. A great service would be rendered also by sending ethnographical objects, photographs, models, &c., which will be entrusted to the care of the Ethnological Museum.

From a Report on the means employed in France for protecting the vine from destruction by the Phylloxera, by Mr. C. H. Perceval, H.M. Consul at Bordeaux, we take the following interesting extract:—"The information which I have gathered on this subject, from official and other sources, tends to reduce the methods used to the following three:—firstly, submersion of the vineyard, when practicable; secondly, by employing insecticides; and, thirdly, where the vineyards have been destroyed, by the plantation of American varieties of vines, whose roots offer more resistance to the attack of the insect. M. Armand Lalande, the President of the Chamber of Commerce of Bordeaux, proprietor of extensive vineyards in the Médoc, a gentleman to whom I am much indebted for the information and assistance which he has been kind enough to afford me in drawing up this Report, addressed a meeting of that body held in March last on various topics, and I translate the following from his remarks regarding the Phylloxera:—'The Chamber of Commerce has not ceased to show the extreme importance which it attaches to all the means employable in combating this dreadful scourge. Of the 2,200,000 hectares which composed the vineyards of France, 500,000 are destroyed, 500,000 others are greatly attacked: it is a loss of more than three milliards to the country. The Gironde is one of the departments which has suffered most: one-third of the vineyards are destroyed, another third is badly attacked. We must admit, with sorrow, that the very sources of our commerce and of the well-being of our southern population are most seriously compromised. Still we have great hopes that, by energetic and intelligent efforts, we may be enabled gradually to arrest and repair the evil. For the very important vineyards of the Gironde, where submersion is possible, it is a sure remedy, which is generally employed, and with invariable success. In the cases of vineyards already destroyed, the remedy seems to be, to reconstitute them by planting American vines as stocks for grafting French cuttings on, which plan has been the subject of satisfactory and conclusive experiments for the last few years, especially in Languedoc. Where the vines are not too far gone, a judicious use of sulphur of carbon is a certain means of preservation, and, in most cases, practicable, owing to the moderation of the cost.' He then states that he bases his opinion on astonishing and conclusive results, which he has observed in immense vineyards in Languedoc, and also in others of the Gironde, and proposes that steps may be taken to hold an international congress on Phylloxera here in the autumn." The Congress is to open on September 5. As we intimated last week, another Viticultural Congress meets in Milan next week. Mr. Perceval gives some valuable details on the various methods of treating the disease.

MM. Koch and Klocke, who have continued during the summer of 1880 their interesting observations on the motion of the Morteratsch glacier, publish their results in the eighth volume of the *Proceedings* of the Natural History Society of Freiburg. They have measured each half-hour during a fortnight the motion of a point on the glacier, and this year, as well as during the foregoing year, their results are almost negative, *i.e.* the motion was so slow, and the advance of their signal-stick was so small and often even negative, that nothing can be inferred until now as to the motion of this glacier. Thus observing, for instance, the advance of their signal each half hour, on September 11, from midday to six o'clock in the evening, they find the following figures, in millimetres: 0·5, −0·5, −0·5, 0·5, 0·0, 0·2, −0·2, 0·2, −1·0, 1·3, −1·5, −1·5, the negative figures showing a back movement of the signal. Therefore MM. Koch and Klocke have undertaken a thorough verification of their instruments, and they have arrived at the conclusion that the motion observed cannot be attributed to errors of observation. Besides they have devised a special arrangement for keeping their signal motionless in the ice; they sink into the ice of the glacier a large copper tube which is filled with ice and salt, and covered by a small hill of ice, and only then they adjust their scale on the tube. This signal remaining firm throughout the day in the ice, the theodolite being also motionless, and the probable errors of observation not exceeding 0·3 millimetres, the small observed motions must be attributed, they suppose, to some cause yet unknown.

At a recent preliminary meeting at Fishmongers' Hall it was resolved to hold a public meeting in the above hall on Friday, August 5, to make arrangements for holding an International Fisheries Exhibition in 1883.

Under the superintendence of Mr. Wallace, rector of Inverness High School, several of the scientific societies of Northern Scotland met at Elgin on July 29 and 30. Several papers were

read and excursions made to places of interest in the neighbourhood, and the meeting seems to have been altogether satisfactory. Arrangements were made to hold a similar meeting next year at Inverness.

THE Annual Meeting of the British Medical Association was opened on Tuesday at Ryde, Isle of Wight.

ANOTHER smart earthquake shock, not so strong however as the last, was felt at Geneva on Friday morning. Three earthquake shocks were felt on Thursday night at Allevard, near Grenoble. An undulatory shock of earthquake was felt at Agram on July 28 at 11h. 8m. a.m. Its direction was from south-east to north-west, and subterranean noise accompanied it. Earthquakes are also reported from Haiti on July 5 and 7, from St. Vincent June 24 and 25, and from Trinidad on June 29.

THE Annual Report of the Paris Observatory for the year 1880 has just been published by the director, Admiral Mouchez. The chief work of the Observatory was the continuation of the revision of the Catalogue of Stars of Lalande; and of the 30,000 observations which were made by the meridian instruments 28,331 were made for this purpose. Until this is finished, the Observatory cannot undertake any other great work; and a catalogue of 20,000 stars observed two or three times up to the end of 1879 is already prepared. As to the precise determination of positions of the fundamental stars, it is not yet begun, the astronomers being engaged in the study of the errors of instruments. M. Loewy has continued the study of the flexion of the meridional instruments, and the error for the larger one was found to be about 0·02 mm., that is about one second of arc. But M. Mouchez expresses the fear that this small error will be less than several accidental errors depending upon changes of temperature, upon the movements of the telescope and upon the errors of refraction due to imperfect observations of temperature at various heights. The great equatorial telescope was but little used, mainly because of the difficulties of management of the revolving tower. With the other equatorial telescopes the astronomers of the Observatory continued their work on the ecliptical charts, as well as of Jupiter, of the comets, of several small planets, and of double stars. The great telescope was employed for the first time during last year for photography; the photographs of the moon, not, however, as fine as those of Rutherfurd—will probably be soon much improved; several photographs of double stars, and even of nebulæ, were obtained. The most interesting work in physical astronomy was done by M. Thollon with the spectroscope: one of the protuberances he studied was rather remarkable by its immense length of eight minutes, that is of 300,000 kilometres. Much attention was given to the transmission of time to the clocks of the Observatory itself, of Paris, and of provincial towns. The astronomical museum, which will be opened at the Observatory, will soon be quite finished; it will contain a variety of instruments formerly used by renowned astronomers, numerous photographs of instruments of different observatories, and portraits; as to these last, the Report speaks in high terms of the courtesy of several astronomers in England, who have given all facilities for the execution of portraits from originals in their possession. After mentioning the various works pursued by the astronomers of the Observatory, besides their regular business, the Report speaks of the preparations for the observation of the transit of Venus in 1882. None of the methods employed until now have given quite satisfactory results, and the simple observation by telescope may yield errors of as much as ten and fifteen seconds. The photographs, which it was necessary to enlarge thirty and forty times, do not afford the necessary cleanliness. Thus the Observatory proposes to employ micrometrical measures which will afford a greater degree of accuracy when done by telescopes than those which are taken on photographs.

THE opening of the Période "Electorale" has directed the attention of the French Government to the opportunity of connecting the municipal telegraphic system of Paris with the postal organisation. It will be the work of a few days, and of a few hundred pounds.

FROM a privately issued report on silk cultivation in the Chinese province of Kwangtung, we learn that in the Pakhoi district, on the southern seaboard, wild silkworms are found which feed on the camphor tree, and their silk is utilised in a singular manner. When the caterpillar has attained its full size, and is about to enter the *pupa* state, it is cut open and the silk extracted in a form much resembling catgut. This substance, having undergone a process of hardening, makes excellent fish line, and is generally used for that purpose in the Pakhoi district.

FROM the *Colonies and India* we learn that a thick vein of a peculiar substance, which, according to local chemists, contains 50 per cent. of pure paraffin, has been discovered at Hawkes Bay, New Zealand. It is said to be worth 40*l*. per ton, and to exist in enormous quantities.

THE latest excavations made by order of the Athens Archæological Society at Tanagra, the well-known place in Bœotia whence come the charming terra-cotta figures, have yielded important results. On the northern side of the town, in front of the principal gate, fifteen tombs were discovered which were completely untouched. They contained some sixty clay figures, most of them perfect, and measuring between 10 and 35 centimetres in height. They represent satyrs and women standing and sitting, and one is a group of two figures. Besides these many vessels were found, amongst which some twenty lekythoi (paint and oil phials) with antique-painted ornaments. Unfortunately most of these were broken. One vase which was found in a stone case shows an artistic inscription which designates it as a work of Teisias. We may also mention that fourteen scraping irons were found, and also that in two of the tombs some fifty small terra-cotta ornaments were discovered, most of which were brightly coloured, and some covered with thin gold. The excavations became even more important after April 1. The published report mentions twenty vessels, some broken, ten of which are ornamented with paintings. Two of these are said to be particularly fine. Of the numerous clay figures only eight could be got out in a tolerably perfect condition. Of these two are reported to be the most perfect figures ever found at Tanagra. One represents a winged youth who is about to raise himself into the air; before him is a maiden on her knees, her dress forming an arc above her; the youth holds her by the arms as if he wished to take her along with him in his flight. The other masterpiece is an Aphrodite rising from the sea, diving up out of a shell as it were.

THE additions to the Zoological Society's Gardens during the past week include a Polecat (*Mustela putorius*), British, presented by Mr. H. C. Brooke; two Ground Squirrels (*Xerus getulus*) from West Africa, presented by Dr. W. Hume Hart; a Bateleur Eagle (*Helotarsus ecaudatus*) from Africa, presented by Mr. William Waters; a Black-footed Penguin (*Spheniscus demersus*) from South Africa, presented by Capt. Robinson, R.M.S. *Warwick Castle*; two Black Storks (*Ciconia nigra*), European, presented by Dr. Rudolph Blasius; two Wood Owls (*Syrnium aluco*), European, presented by Mr. H. T. Archer; a Slow worm (*Anguis fragilis* albino), British, presented by Mr. A. Phipson, F.Z.S.; two Green Lizards (*Lacerta viridis*) from the Island of Jersey, presented by Mr. Claud Russell; a Sykes Monkey (*Cercopithecus albigularis*) from East Africa, a Common Chamæleon (*Chamæleon vulgaris*) from North Africa, deposited; an Erxleben's Monkey (*Cercopithecus erxlebeni*) from West Africa, two Egyptian Mastigures (*Uromastix spinipes*) from North Africa, two Aldrovandi's Skinks (*Plestiodon auratus*) from

North-West Africa, two Pantherine Toads (*Bufo pantherinus*) from Tunis, on approval; a Bennett's Wallaby (*Halmaturus bennetti*), born in the Gardens. In the Insectarium may now be seen larvæ of the scarce Swallow-tail Butterfly (*Papilio podalirius*), also those of *Attacus atlas* of various sizes, from ones just hatched to ones nearly full-fed. Other noticeable larvæ are the curiously shaped ones of *Stauropus fagi*, and young ones of the North American *Samia cecropia*. Imagos of *Attacus pernyi* are also emerging, reared from eggs laid in the Insectarium in the earlier part of the summer.

OUR ASTRONOMICAL COLUMN

GOULD'S COMET-OBSERVATIONS ON JUNE 11.—Dr. B. A. Gould, director of the Observatory at Cordoba, has communicated to the *Astronomische Nachrichten* particulars of his experiences while observing the great comet of the present year on the evening of June 11. On that evening, he says, "the comet was found with but little difficulty, although considerably north of the estimated place, being recognisable by its diffuse aspect, elongated form, and large diameter, although it was quite pale in the bright twilight, and the tail could not be seen." He had just obtained a rough determination of its position from the equatorial circles for the purpose of finding and identifying some comparison-star, when he found one in the field. He considered it to be some one of the many bright stars of Orion in the vicinity, which would be readily identified, and hence did not complete the approximate determination with the usual care, nor obtain instrumental readings for the star. This he describes as "only a little fainter than the comet itself, and not very dissimilar in aspect: since, although its apparent diameter was much less than the comet's, it was greatly blurred by the exceptionally thick haze and the mists of the horizon, the zenith distance being nearly 80°, I do not think it would have been below the third magnitude, and could rather believe it to have been as bright as the second." Dr. Gould adds: "Only four comparisons were obtained before the comet passed below the horizon; then on attempting to identify the star, I found it in none of the catalogues."

On the next evening he examined the region without finding any visible star, but Rigel was much brighter than the missing object, and there was no visible object in the vicinity of the comet, which he found nearly three degrees to the northward.

The observations gave the following results:—

1881, June 11, position of the comet from the circles of the equatorial. 10h. 58m. 9s. sidereal time. Right ascension, 5h. 11m. 4s. Decl. − 9° 36′.

The comparisons with the star gave:—(Comet—star.)

Cordoba Sid. T.	Diff. R.A.	Diff. Decl.	
h. m. s.	m. s.	″	
11 8 49 ...	+ 0 49 ...	− 16·40	One revolution
11 11 2·5 ...	49 ...	16·16	of micrometer
11 13 11·0 ...	48 ...	16·17	= 19′·08.
11$_m$14 37·5 ...	48·5 ...	15·87	
11 11 55 ...	+ 0 48·6 ...	− 16·15 (− 5′ 8″·1).	

Thus he deduced for the star's position R.A. 5h. 10m. 16s. Decl. − 9° 30′, where our catalogues have no conspicuous star. In his letter to Prof. Krueger he concludes thus:—

"The whole observation has seemed to me so improbable that I have hesitated a good deal before sending it to you, fearing some gross error in reading the circles. But I have discovered none, and the later determination of the comet's geocentric path will remove all uncertainties of this kind."

On receiving these particulars Prof. Krueger, determined the place of the comet for the time of Dr. Gould's observation, from the elements we published in this column, which were founded upon observations between June 22 and July 1, and finds R.A. 5h. 11m. 15s., Decl. − 9° 32′·0, and thence for the place of the star R.A. 5h. 10m. 26s., Decl. − 9° 26′·9, showing only such differences from the observed place as might be well attributed to uncertainty of observation so near the horizon, and to the corrections which the elements used probably required before the perihelion passage. Prof. Krueger remarks that no known bright star exists in this position, and the star-chart of the Berlin Academy for this region, which was formed by Dr. Schmidt, shows here a great blank. He draws attention also to the significant fact that the observed motion in declination in the interval between the first and last comparisons is much less than that which the comet must have had; the elements would indicate about 45″ or more than 2·3 revolutions of the micrometer-screw, while the observations give only 0·5. Dr. Gould especially remarks upon the resemblance of the object to the comet, and Prof. Krueger suggests whether there could have been "eine Verdoppelung des Cometen in Folge einer Luftspiegelung," or again was a *second comet* observed?

The case is a very interesting one. With elements which must give the comet's place on June 11 within a very few seconds of arc, Prof. Krueger's inferences are fully borne out. Thus for June 11·41962, Greenwich mean time, which corresponds to 11h. 11m. 55s. Cordoba sidereal time, diminished by the time for aberration, the right ascension of the comet is found to have been 5h. 11m. 13·0s., Decl. − 9° 35′ 18″, agreeing closely with Dr. Gould's instrumental place obtained a few minutes earlier, and the differential observations thus give for the apparent position of the star, R.A. 5h. 10m. 24·4s., Decl. − 9° 30′ 10″. There appears to be a misprint or an oversight in Dr. Gould's letter as regards the zenith distance of the comet and neighbouring object at the time of his observations, which would be nearer 85° than 80°.

SCHÄBERLE'S COMET.—The following elements of this comet have been calculated by M. Bigourdan, of the Observatory at Paris, from observations on July 18, 23, and 28:—

Perihelion passage, 1881, August 22·60205, M.T. at Paris.

Longitude of perihelion	334° 41′ 10″	M.Eq. 1881·0
,, ascending node	96 48 23	
Inclination	39 56 38	
Log. perihelion distance	9·8017 88	

Motion—retrograde.

Whence the comet's positions for midnight at Berlin, or about 11h. 6m. G.M.T., will be:—

	R.A.	Decl.	Log. Distance from	
	h. m. s.	° ′	Earth.	Sun.
August 11 ...	7 54 0 ...	+52 7·6 ...	9·9307 ...	9·8307
13 ...	8 22 55 ...	52 45·6 ...	9·8973 ...	9·8218
15 ...	8 57 39 ...	52 47·2 ...	9·8638 ...	9·8142
17 ...	9 37 38 ...	51 51·4 ...	9·8317 ...	9·8083
19 ...	10 20 39 ...	49 36·7 ...	9·8031 ...	9·8043
21 ...	11 3 21 ...	+45 49·6 ...	9·7806 ...	9·8020

The comet was within naked eye vision on the morning of July 29, and the intensity of light, according to theory, should increase until August 25, about which time we may look for a pretty conspicuous object. The most favourable period for observation will be during the last ten days of August.

THE CONNECTION OF THE BIOLOGICAL SCIENCES WITH MEDICINE[1]

THE great body of theoretical and practical knowledge which has been accumulated by the labours of some eighty generations, since the dawn of scientific thought in Europe, has no collective English name to which an objection may not be raised; and I use the term "medicine" as that which is least likely to be misunderstood; though, as every one knows, the name is commonly applied, in a narrower sense, to one of the chief divisions of the totality of medical science.

Taken in this broad sense, "medicine" not merely denotes a kind of knowledge; but it comprehends the various applications of that knowledge to the alleviation of the sufferings, the repair of the injuries, and the conservation of the health, of living beings. In fact, the practical aspect of medicine so far dominates over every other, that the "Healing Art" is one of its most widely received synonyms. It is so difficult to think of medicine otherwise than as something which is necessarily connected with curative treatment, that we are apt to forget that there must be, and is, such a thing as a pure science of medicine—a "pathology" which has no more necessary subservience to practical ends than has zoology or botany.

The logical connection between this purely scientific doctrine of disease, or pathology, and ordinary biology, is easily traced. Living matter is characterised by its innate tendency to exhibit a definite series of the morphological and physiological phenomena which constitute organisation and life. Given a certain range of conditions, and these phenomena remain the same, within narrow limits, for each kind of living thing. They

[1] Address at the International Medical Congress. By Prof. T. H. Huxley, LL.D., Secretary to the Royal Society.

furnish the normal and typical characters of the species; and, as such, they are the subject matter of ordinary biology.

Outside the range of these conditions, the normal course of the cycle of vital phenomena is disturbed; abnormal structure makes its appearance, or the proper character and mutual adjustment of the functions cease to be preserved. The extent and the importance of these deviations from the typical life may vary indefinitely. They may have no noticeable influence on the general well-being of the economy, or they may favour it. On the other hand, they may be of such a nature as to impede the activities of the organism, or even to involve its destruction.

In the first case, these perturbations are ranged under the wide and somewhat vague category of "variations"; in the second, they are called lesions, states of poisoning, or diseases; and, as morbid states, they lie within the province of pathology. No sharp line of demarcation can be drawn between the two classes of phenomena. No one can say where anatomical variations end and tumours begin, nor where modification of function, which may at first promote health, passes into disease. All that can be said is, that whatever change of structure or function is hurtful belongs to pathology. Hence it is obvious that pathology is a branch of biology; it is the morphology, the physiology, the distribution, the ætiology of abnormal life.

However obvious this conclusion may be now, it was nowise apparent in the infancy of medicine. For it is a peculiarity of the physical sciences, that they are independent in proportion as they are imperfect; and it is only as they advance that the bonds which really unite them all become apparent. Astronomy had no manifest connection with terrestrial physics before the publication of the "Principia"; that of chemistry with physics is of still more modern revelation; that of physics and chemistry, with physiology, has been stoutly denied within the recollection of most of us, and perhaps still may be.

Or, to take a case which affords a closer parallel with that of medicine. Agriculture has been cultivated from the earliest times; and, from a remote antiquity, men have attained considerable practical skill in the cultivation of the useful plants, and have empirically established many scientific truths concerning the conditions under which they flourish. But it is within the memory of many of us that chemistry on the one hand, and vegetable physiology on the other, attained a stage of development such that they were able to furnish a sound basis for scientific agriculture. Similarly, medicine took its rise in the practical needs of mankind. At first, studied without reference to any other branch of knowledge, it long maintained, indeed still to some extent maintains, that independence. Historically, its connection with the biological sciences has been slowly established, and the full extent and intimacy of that connection are only now beginning to be apparent. I trust I have not been mistaken in supposing that an attempt to give a brief sketch of the steps by which a philosophical necessity has become a historical reality, may not be devoid of interest, possibly of instruction, to the members of this great Congress, profoundly interested as all are in the scientific development of medicine.

The history of medicine is more complete and fuller than that of any other science, except perhaps astronomy; and if we follow back the long record as far as clear evidence lights us, we find ourselves taken to the early stages of the civilisation of Greece. The oldest hospitals were the temples of Æsculapius; to these Asclepeia, always erected on healthy sites, hard by fresh springs and surrounded by shady groves, the sick and the maimed resorted to seek the aid of the god of health. Votive tablets or inscriptions recorded the symptoms, no less than the gratitude, of those who were healed; and, from these primitive clinical records, the half-priestly, half-philosophic, caste of the Asclepiads compiled the data upon which the earliest generalisations of medicine, as an inductive science, were based.

In this state, pathology, like all the inductive sciences at their origin, was merely natural history; it registered the phenomena of disease, classified them, and ventured upon a prognosis, wherever the observation of constant co-existences and sequences, suggested a rational expectation of the like recurrence under similar circumstances.

Further than this, it hardly went. In fact, in the then state of knowledge and in the condition of philosophical speculation at that time, neither the causes of the morbid state, nor the *rationale* of treatment, were likely to be sought for as we seek for them now. The anger of a God was a sufficient reason for the existence of a malady, and a dream ample warranty for therapeutic measures; that a physical phenomenon must needs have a physical cause was not the implied or expressed axiom that it is to us moderns.

The great man, whose name is inseparately connected with the foundation of medicine, Hippocrates, certainly knew very little, indeed practically nothing, of anatomy or physiology; and he would probably have been perplexed, even to imagine the possibility of a connection between the zoological studies of his contemporary, Democritus, and medicine. Nevertheless, in so far as he, and those who worked before and after him, in the same spirit, ascertained, as matters of experience, that a wound, or a luxation, or a fever, presented such and such symptoms, and that the return of the patient to health was facilitated by such and such measures, they established laws of nature, and began the construction of the science of pathology.—All true science begins with empiricism—though all true science is such exactly, in so far as it strives to pass out of the empirical stage into that of the deduction of empirical from more general truths. Thus, it is not wonderful that the early physicians had little or nothing to do with the development of biological science; and, on the other hand, that the early biologists did not much concern themselves with medicine. There is nothing to show that the Asclepiads took any prominent share in the work of founding anatomy, physiology, zoology, and botany. Rather do these seem to have sprung from the early philosophers, who were essentially natural philosophers, animated by the characteristically Greek thirst for knowledge as such. Pythagoras, Alcmeon, Democritus, Diogenes of Apollonia, are all credited with anatomical and physiological investigation; and though Aristotle is said to have belonged to an Asclepiad family, and not improbably owed his taste for anatomical and zoological inquiries to the teachings of his father, the physician Nicomachus, the "Historia Animalium," and the treatise "De Partibus Animalium," are as free from any allusion to medicine, as if they had issued from a modern biological laboratory.

It may be added, that it is not easy to see in what way it could have benefited a physician of Alexander's time to know all that Aristotle knew on these subjects. His human anatomy was too rough to avail much in diagnosis, his physiology was too erroneous to supply data for pathological reasoning. But when the Alexandrian school, with Erasistratus and Herophilus at their head, turned to account the opportunities of studying human structure, afforded to them by the Ptolemies, the value of the large amount of accurate knowledge thus obtained to the surgeon for his operations, and to the physician for his diagnosis of internal disorders, became obvious, and a connection was established between anatomy and medicine, which has ever become closer and closer. Since the revival of learning, surgery, medical diagnosis, and anatomy have gone hand in hand. Morgagni called his great work, "De sedibus et causis morborum per anatomen indagatis," and not only showed the way to search out the localities and the causes of disease by anatomy, but himself travelled wonderfully far upon the road. Bichat, discriminating the grosser constitutents of the organs and parts of the body, one from another, pointed out the direction which modern research must take; until, at length, histology, a science of yesterday, as it seems to many of us, has carried the work of Morgagni as far as the microscope can take us, and has extended the realm of pathological anatomy to the limits of the invisible world.

Thanks to the intimate alliance of morphology with medicine, the natural history of disease has, at the present day, attained a high degree of perfection. Accurate regional anatomy has rendered practicable the exploration of the most hidden parts of the organism, and the determination during life of morbid changes in them; anatomical and histological post-mortem investigations have supplied physicians with a clear basis upon which to rest the classification of diseases, and with unerring tests of the accuracy or inaccuracy of their diagnoses.

If men could be satisfied with pure knowledge, the extreme precision with which, in these days, a sufferer may be told what is happening and what is likely to happen, even in the most recondite parts of his bodily frame, should be as satisfactory to the patient, as it is to the scientific pathologist who gives him the information. But I am afraid it is not; and even the practising physician, while no wise underestimating the regulative value of accurate diagnosis, must often lament that so much of his knowledge rather prevents him from doing wrong, than helps him to do right.

A scorner of physic once said that nature and disease may be compared to two men fighting, the doctor to a blind man with a club, who strikes into the *melée*, sometimes hitting the disease,

and sometimes hitting nature. The matter is not mended if you suppose the blind man's hearing to be so acute that he can register every stage of the struggle and pretty clearly predict how it will end. He had better not meddle at all, until his eyes are opened—until he can see the exact position of the antagonists, and make sure of the effect of his blows. But that which it behoves the physician to see, not indeed with his bodily eye, but with clear intellectual vision, is a process, and the chain of causation involved in that process. Disease, as we have seen, is a perturbation of the normal activities of a living body; and it is, and must remain, unintelligible, so long as we are ignorant of the nature of these normal activities.—In other words, there could be no real science of pathology, until the science of physiology had reached a degree of perfection unattained, and indeed unattainable, until quite recent times.

So far as medicine is concerned, I am not sure that physiology, such as it was down to the time of Harvey, might as well not have existed. Nay, it is perhaps no exaggeration to say, that within the memory of living men, justly renowned practitioners of medicine and surgery knew less physiology than is now to be learned from the most elementary text-book; and, beyond a few broad facts, regarded what they did know, as of extremely little practical importance. Nor am I disposed to blame them for this conclusion; physiology must be useless, or worse than useless, to pathology, so long as its fundamental conceptions are erroneous.

Harvey is often said to be the founder of modern physiology; and there can be no question that the elucidations of the function of the heart, of the nature of the pulse, and of the course of the blood, put forth in the ever-memorable little essay "De motu cordis," directly worked a revolution in men's views of the nature and of the concatenation of some of the most important physiological processes among the higher animals; while, indirectly, their influence was perhaps even more remarkable.

But, though Harvey made this signal and perennially important contribution to the physiology of the moderns, his general conception of vital processes was essentially identical with that of the ancients; and, in the "Exercitationes de generatione," and notably in the singular chapter "De calido innato," he shows himself a true son of Galen and of Aristotle.

For Harvey, the blood possesses powers superior to those of the elements; it is the seat of a soul which is not only vegetative, but also, sensitive and motor. The blood maintains and fashions all parts of the body, "idque summâ cum providentiâ et intellectu in finem certum agens, quasi ratiocinio quodam uteretur."

Here is the doctrine of the "pneuma," the product of the philosophical mould into which the animism of primitive men ran in Greece, in full force. Nor did its strength abate for long after Harvey's time. The same ingrained tendency of the human mind to suppose that a process is explained when it is ascribed to a power of which nothing is known except that it is the hypothetical agent of the process, gave rise in the next century to the animism of Stahl; and, later, to the doctrine of a vital principle, that "asylum ignorantiæ" of physiologists, which has so easily accounted for everything and explained nothing, down to our own times.

Now the essence of modern, as contrasted with ancient, physiological science, appears to me to lie in its antagonism to animistic hypotheses and animistic phraseology. It offers physical explanations of vital phenomena, or frankly confesses that it has none to offer. And so far as I know, the first person who gave expression to this modern view of physiology, who was bold enough to enunciate the proposition that vital phenomena, like all the other phenomena of the physical world, are, in ultimate analysis, resolvable into matter and motion, was René Descartes.

The fifty-four years of life of this most original and powerful thinker are widely overlapped, on both sides, by the eighty of Harvey, who survived his younger contemporary by seven years, and takes pleasure in acknowledging the French philosopher's appreciation of his great discovery.

In fact, Descartes accepted the doctrine of the circulation as propounded by "Hervæus, médecin d'Angleterre," and gave a full account of it in his first work, the famous "Discours de la Méthode," which was published in 1637, only nine years after the exercitation "De motu cordis"; and, though differing from Harvey in some important points (in which it may be noted, in passing, Descartes was wrong and Harvey right), he always speaks of him with great respect. And so important does the subject seem to Descartes, that he returns to it in the "Traité des Passions," and in the "Traité de l'Homme."

It is easy to see that Harvey's work must have had a peculiar significance for the subtle thinker, to whom we owe both the spiritualistic and the materialistic philosophies of modern times. It was in the very year of its publication, 1628, that Descartes withdrew into that life of solitary investigation and meditation of which his philosophy was the fruit. And, as the course of his speculations led him to establish an absolute distinction of nature between the material and the mental worlds, he was logically compelled to seek for the explanation of the phenomena of the material world within itself; and having allotted the realm of thought to the soul, to see nothing but extension and motion in the rest of nature. Descartes uses "thought" as the equivalent of our modern term "consciousness." Thought is the function of the soul, and its only function. Our natural heat and all the movements of the body, says he, do not depend on the soul. Death does not take place from any fault of the soul, but only because some of the principal parts of the body become corrupted. The body of a living man differs from that of a dead man in the same way as a watch or other automaton (that is to say a machine which moves of itself) when it is wound up and has in itself the physical principle of the movements which the mechanism is adapted to perform, differs from the same watch, or other machine, when it is broken and the physical principle of its movement no longer exists. All the actions which are common to us and the lower animals depend only on the conformation of our organs and the course which the animal spirits take in the brain, the nerves, and the muscles; in the same way as the movement of a watch is produced by nothing but the force of its spring and the figure of its wheels and other parts.

Descartes' Treatise on Man is a sketch of human physiology in which a bold attempt is made to explain all the phenomena of life, except those of consciousness, by physical reasonings. To a mind turned in this direction, Harvey's exposition of the heart and vessels as a hydraulic mechanism must have been supremely welcome.

Descartes was not a mere philosophical theorist, but a hard-working dissector and experimenter, and he held the strongest opinion respecting the practical value of the new conception which he was introducing. He speaks of the importance of preserving health, and of the dependence of the mind on the body being so close that perhaps the only way of making men wiser and better than they are, is to be sought in medical science. "It is true," says he, "that as medicine is now practised, it contains little that is very useful; but without any desire to depreciate, I am sure that there is no one, even among professional men, who will not declare that all we know is very little as compared with that which remains to be known; and that we might escape an infinity of diseases of the mind, no less than of the body, and even perhaps from the weakness of old age, if we had sufficient knowledge of their causes, and of all the remedies with which nature has provided us."[1] So strongly impressed was Descartes with this, that he resolved to spend the rest of his life in trying to acquire such a knowledge of nature as would lead to the construction of a better medical doctrine.[2] The anti-Cartesians found material for cheap ridicule in these aspirations of the philosopher: and it is almost needless to say that, in the thirteen years which elapsed between the publication of the "Discours" and the death of Descartes, he did not contribute much to their realisation. But, for the next century, all progress in physiology took place along the lines which Descartes laid down.

The greatest physiological and pathological work of the seventeenth century, Borelli's treatise "De motu animalium," is, to all intents and purposes, a development of Descartes' fundamental conception; and the same may be said of the physiology and pathology of Boerhaave, whose authority dominated in the medical world of the first half of the eighteenth century.

With the origin of modern chemistry, and of electrical science, in the latter half of the eighteenth century, aids in the analysis of the phenomena of life, of which Descartes could not have dreamed, were offered to the physiologist. And the greater part of the gigantic progress which has been made in the present century, is a justification of the prevision of Descartes. For it consists, essentially, in a more and more complete resolution of the grosser organs of the living body into physico-chemical mechanisms.

[1] "Discours de la Méthode," 6e partie, Ed. Cousin, p. 193.
[2] *Ibid.* pp. 193 and 211.

"I shall try to explain our whole bodily machinery in such a way, that it will be no more necessary for us to suppose that the soul produces such movements as are not voluntary, than it is to think that there is in a clock a soul which causes it to show the hours."[1] These words of Descartes might be appropriately taken as a motto by the author of any modern treatise on physiology.

But though, as I think, there is no doubt that Descartes was the first to propound the fundamental conception of the living body as a physical mechanism, which is the distinctive feature of modern, as contrasted with ancient physiology, he was misled by the natural temptation to carry out, in all its details, a parallel between the machines with which he was familiar, such as clocks and pieces of hydraulic apparatus, and the living machine. In all such machines there is a central source of power, and the parts of the machine are merely passive distributors of that power. The Cartesian school conceived of the living body as a machine of this kind; and herein they might have learned from Galen, who, whatever ill use he may have made of the doctrine of "natural faculties," nevertheless had the great merit of perceiving that local forces play a great part in physiology.

The same truth was recognised by Glisson, but it was first prominently brought forward in the Hallerian doctrine of the "vis insita" of muscles. If muscle can contract without nerve, there is an end of the Cartesian mechanical explanation of its contraction by the influx of animal spirits.

The discoveries of Trembley tended in the same direction. In the freshwater *Hydra*, no trace was to be found of that complicated machinery upon which the performance of the functions in the higher animals was supposed to depend. And yet the hydra moved, fed, grew, multiplied, and its fragments exhibited all the powers of the whole. And, finally, the work of Caspar F. Wolff,[2] by demonstrating the fact that the growth and development of both plants and animals take place antecedently to the existence of their grosser organs, and are, in fact, the causes and not the consequences of organisation (as then understood), sapped the foundations of the Cartesian physiology as a complete expression of vital phenomena.

For Wolff, the physical basis of life is a fluid, possessed of a "vis essentialis" and a "solidescibilitas," in virtue of which it gives rise to organisation; and, as he points out, this conclusion strikes at the root of the whole iatro-mechanical system.

In this country, the great authority of John Hunter exerted a similar influence; though it must be admitted that the two sibylline utterances which are the outcome of Hunter's struggles to define his conceptions are often susceptible of more than one interpretation. Nevertheless, on some points, Hunter is clear enough. For example, he is of opinion that "Spirit is only a property of matter" ("Introduction to Natural History," p. 6), he is prepared to renounce animism (*l. c.* p. 8), and his conception of life is so completely physical that he thinks of it as something which can exist in a state of combination in the food. "The aliment we take in has in it, in a fixed state, the real life; and this does not become active until it has got into the lungs; for there it is freed from its prison" ("Observations on Physiology," p. 113). He also thinks that "It is more in accord with the general principles of the animal machine to suppose that none of its effects are produced from any mechanical principle whatever; and that every effect is produced from an action in the part; which action is produced by a stimulus upon the part which acts, or upon some other part with which this part sympathises so as to take up the whole action" (*l.c.* p. 152).

And Hunter is as clear as Wolff, with whose work he was probably unacquainted, that "whatever life is, it most certainly does not depend upon structure or organisation" (*l.c.* p. 114).

Of course it is impossible that Hunter could have intended to deny the existence of purely mechanical operations in the animal body. But while, with Borelli and Boerhaave, he looked upon absorption, nutrition, and secretion, as operations effected by means of the small vessels; he differed from the mechanical physiologists, who regarded these operations as the result of the mechanical properties of the small vessels, such as the size, form, and disposition of their canals and apertures. Hunter, on the contrary, considers them to be the effect of properties of these vessels which are not mechanical but vital. "The vessels," says he, "have more of the polypus in them than any other part of the body," and he talks of the "living and sensitive principles of the arteries," and even of the "dispositions or feelings of the arteries." "When the blood is good and genuine the sensations of the arteries, or the dispositions for sensation, are agreeable. . . . It is then they dispose of the blood to the best advantage, increasing the growth of the whole, supplying any losses, keeping up a due succession, &c." (*l. c.* p. 133)

If we follow Hunter's conceptions to their logical issue, the life of one of the higher animals is essentially the sum of the lives of all the vessels, each of which is a sort of physiological unit, answering to a polype; and, as health is the result of the normal "action of the vessels," so is disease an effect of their abnormal action. Hunter thus stands in thought, as in time, midway between Borelli, on the one hand, and Bichat on the other.

The acute founder of general anatomy, in fact, outdoes Hunter in his desire to exclude physical reasonings from the realm of life. Except in the interpretation of the action of the sense organs, he will not allow physics to have anything to do with physiology.

"To apply the physical sciences to physiology is to explain the phenomena of living bodies by the laws of inert bodies. Now this is a false principle, hence all its consequences are marked with the same stamp. Let us leave to chemistry its affinity, to physics, its elasticity and its gravity. Let us invoke for physiology only sensibility and contractility."[1]

Of all the unfortunate dicta of men of eminent ability this seems one of the most unhappy, when we think of what the application of the methods and the data of physics and chemistry has done towards bringing physiology into its present state. It is not too much to say that one half of a modern text-book of physiology consists of applied physics and chemistry; and that it is exactly in the exploration of the phenomena of sensibility and contractility that physics and chemistry have exerted the most potent influence.

Nevertheless, Bichat rendered a solid service to physiological progress by insisting upon the fact that what we call life, in one of the higher animals, is not an indivisible unitary archæus dominating, from its central seat, the parts of the organism, but a compound result of the synthesis of the separate lives of those parts.

"All animals," says he, "are assemblages of different organs, each of which performs its function and concurs, after its fashion, in the preservation of the whole. They are so many special machines in the general machine which constitutes the individual. But each of these special machines is itself compounded of many tissues of very different natures, which in truth constitute the elements of those organs." (*l.c.* lxxix.) "The conception of a proper vitality is applicable only to these simple tissues, and not to the organs themselves." (*l.c.* lxxxiv.)

And Bichat proceeds to make the obvious application of this doctrine of synthetic life, if I may so call it, to pathology. Since diseases are only alterations of vital properties, and the properties of each tissue are distinct from those of the rest, it is evident that the diseases of each tissue must be different from those of the rest. Therefore, in any organ composed of different tissues, one may be diseased and the other remain healthy; and this is what happens in most cases. (*l.c.* lxxxv.)

In a spirit of true prophecy, Bichat says, "we have arrived at an epoch, in which pathological anatomy should start afresh." For as the analysis of the organs had led him to the tissues, as the physiological units of the organism; so, in a succeeding generation, the analysis of the tissues led to the cell as the physiological element of the tissues. The contemporaneous study of development brought out the same result, and the zoologists and botanists exploring the simplest and the lowest forms of animated beings confirmed the great induction of the cell theory. Thus the apparently opposed views, which have been battling with one another ever since the middle of the last century, have proved to be each half the truth.

The proposition of Descartes that the body of a living man is a machine, the actions of which are explicable by the known laws of matter and motion, is unquestionably largely true. But it is also true, that the living body is a synthesis of innumerable physiological elements, each of which may nearly be described, in Wolff's words, as a fluid possessed of a "vis essentialis," and a "solidescibilitas"; or, in modern phrase, as protoplasm susceptible of structural metamorphosis and functional metabolism: and that the only machinery, in the precise sense in which the Cartesian school understood mechanism, is, that which co-ordinates and regulates these physiological units into an organic whole.

[1] "De la Formation du Fœtus."
[2] "Theoria Generationis," 1759.

[1] "Anatomie générale," i. p. liv.

In fact, the body is a machine of the nature of an army, not of that of a watch, or of a hydraulic apparatus. Of this army, each cell is a soldier, an organ a brigade, the central nervous system head-quarters and field telegraph, the alimentary and circulatory system the commissariat. Losses are made good by recruits born in camp, and the life of the individual is a campaign, conducted successfully for a number of years, but with certain defeat in the long run.

The efficacy of an army, at any given moment, depends on the health of the individual soldier, and on the perfection of the machinery by which he is led and brought into action at the proper time; and, therefore, if the analogy holds good, there can be only two kinds of diseases, the one dependent on abnormal states of the physiological units, the other on perturbation of their co-ordinating and alimentative machinery.

Hence, the establishment of the cell theory, in normal biology, was swiftly followed by a "cellular pathology," as its logical counterpart. I need not remind you how great an instrument of investigation, this doctrine has proved in the hands of the man of genius, to whom its development is due; and who would probably be the last to forget that abnormal conditions of the co-ordinative and distributive machinery of the body are no less important factors of disease.

Henceforward, as it appears to me, the connection of medicine with the biological sciences is clearly defined. Pure pathology is that branch of biology which defines the particular perturbation of cell life, or of the co-ordinating machinery, or of both, on which the phenomena of disease depend.

Those who are conversant with the present state of biology will hardly hesitate to admit that the conception of the life of one of the higher animals as the summation of the lives of a cell aggregate, brought into harmonious action by a co-ordinative machinery formed by some of these cells, constitutes a permanent acquisition of physiological science. But the last form of the battle between the animistic and the physical views of life is seen in the contention whether the physical analysis of vital phenomena can be carried beyond this point or not.

There are some to whom living protoplasm is a substance even such as Harvey conceived the blood to be, "summâ cum providentiâ et intellectu in finem certum agens, quasi ratiocinio quodam"; and who look, with as little favour as Bichat did, upon any attempt to apply the principles and the methods of physics and chemistry to the investigation of the vital processes of growth, metabolism, and contractility. They stand upon the ancient ways; only, in accordance with that progress towards democracy which a great political writer has declared to be the fatal characteristic of modern times, they substitute a republic formed by a few billion of "animulæ" for the monarchy of the all pervading "anima."

Others, on the contrary, supported by a robust faith in the universal applicability of the principles laid down by Descartes, and seeing that the actions called "vital" are, so far as we have any means of knowing, nothing but changes of place of particles of matter, look to molecular physics to achieve the analysis of the living protoplasm itself into a molecular mechanism. If there is any truth in the received doctrines of physics, that contrast between living and inert matter, on which Bichat lays so much stress, does not exist. In nature, nothing is at rest, nothing is amorphous; the simplest particle of that which men in their blindness are pleased to call "brute matter" is a vast aggregate of molecular mechanisms, performing complicated movements of immense rapidity and sensitively adjusting themselves to every change in the surrounding world. Living matter differs from other matter in degree and not in kind; the microcosm repeats the macrocosm; and one chain of causation connects the nebulous original of suns and planetary systems with the protoplasmic foundation of life and organisation.

From this point of view, pathology is the analogue of the theory of perturbations in astronomy; and therapeutics resolves itself into the discovery of the means by which a system of forces competent to eliminate any given perturbation may be introduced into the economy. And, as pathology bases itself upon normal physiology, so therapeutics rests upon pharmacology; which is, strictly speaking, a part of the great biological topic of the influence of conditions on the living organism and has no scientific foundation apart from physiology.

It appears to me that there is no more hopeful indication of the progress of medicine towards the ideal of Descartes than is to be derived from a comparison of the state of pharmacology, at the present day, with that which existed forty years ago. If we consider the knowledge positively acquired, in this short time, of the *modus operandi* of urari, of atropia, of physostigmin, of veratria, of casca, of strychnia, of bromide of potassium, of phosphorus, there can surely be no ground for doubting that, sooner or later, the pharmacologist will supply the physician with the means of affecting, in any desired sense, the functions of any physiological element of the body. It will, in short, become possible to introduce into the economy a molecular mechanism which, like a very cunningly contrived torpedo, shall find its way to some particular group of living elements, and cause an explosion among them, leaving the rest untouched.

The search for the explanation of diseased states in modified cell life; the discovery of the important part played by parasitic organisms in the ætiology of disease; the elucidation of the action of medicaments by the methods and the data of experimental physiology; appear to me to be the greatest steps which have ever been made towards the establishment of medicine on a scientific basis. I need hardly say they could not have been made except for the advance of normal biology.

There can be no question then as to the nature or the value of the connection between medicine and the biological sciences. There can be no doubt that the future of Pathology and of Therapeutics, and therefore that of Practical Medicine, depend upon the extent to which those who occupy themselves with these subjects are trained in the methods and impregnated with the fundamental truths of Biology.

And, in conclusion, I venture to suggest that the collective sagacity of this Congress could occupy itself with no more important question than with this: How is medical education to be arranged, so that, without entangling the student in those details of the systematist which are valueless to him, he may be enabled to obtain a firm grasp of the great truths respecting animal and vegetable life, without which, notwithstanding all the progress of scientific medicine, he will still find himself an empiric?

ON THE VALUE OF PATHOLOGICAL EXPERIMENTS[1]

As reporter on Medical Education at the last International Medical Congress held in Amsterdam, I raised the question how far the experimental method is necessary to instruction; and the result at which I arrived was that the use of this method to its greatest extent, and especially of vivisection, is an indispensable means.[2] In a still higher measure, however, I had to raise into prominence the importance of this method in research; and, in opposition to those who, with constantly increasing vehemence, brought accusations against the experimental investigators on account of the direction and method of their researches, I was able to say, with the lively assent of the numerous members of the Congress, and without one word in contradiction: "All those who attack vivisection as a means of science have not the least idea of the importance of the science, and much less of the importance of this aid to knowledge."

In the two years which have since passed away, the agitation of the opponents has grown both extensive and important in its object. One country after another has been drawn into their net, and international combinations have been formed, in order by united force to obtain greater results. No increase of satisfaction has been produced by the concessions made in 1876 by the legislation in England. The demands have increased: a petition from the new Leipsic Society for the Protection of Animals, dated March 8 of the present year, desired of the German Reichstag the enactment of a law by which "cruelty to animals under the pretext of scientific research" should be punished "with imprisonment for periods of not less than five weeks to two years, and with simultaneous deprivation of civil rights." All, indeed, do not go so far. Many do not demand that all experiments on living animals should be at once suppressed, but that there should be limitations, some demanding more, others less. But even these do not make it secret that this concession is only provisional; and they demand that even the official laboratories of the universities should be placed under

[1] Address given at the International Medical Congress by Rudolf Virchow, M.D., Professor in the University of Berlin. The Editor of the *British Medical Journal* has kindly allowed us to use his translation of Prof. Virchow's address.

the control of the members of the Society for the Protection of Animals, so that the members may be at liberty to enter the laboratories at any time.

It would be a mischievous delusion to believe that this movement is without prospect of success, and devoid of danger because of its manifest exaggeration. On the contrary, unmistakable signs indicate that it has gained powerful allies, and that there is an increasingly impending danger in many countries that even the State institutions, created expressly for the purpose of experiment, may have the scientific freedom of their methods attacked. So much the more does it seem to be incumbent on the representatives of medical science to defend their position, and to meet international attacks by international weapons. *The most powerful weapon, however, is truth;* and here, above all, *truth founded on competent knowledge.* If we cannot demonstrate our good right before all the world, and come to a mutual agreement on the ground of this right, our cause must henceforth be looked on as a lost one.

The attacks which are directed against us fall, when closely examined, into two categories, according to the principal point. On the one side it is alleged that the experimental method—yea, modern medicine altogether—is materialistic, if not nihilistic, in its ultimate object; that it offends against sentiment, against morals. On the other side it is denied that the introduction of experiments on animals has had any actual use, that medicine has been really promoted thereby, and especially that the cure of diseases has in consequence made any recognisable progress. Even those who admit that there has been some progress, yet believe that just as much information could have been imparted by anatomy alone as by experiments on living animals.

Such objections are not new to one who knows the history of medicine. For hundreds of years, on similar or identical grounds, the dissection of human bodies was impeded, and anatomists were confined to the dissection of dead animals; if, indeed—as was done by Paracelsus, the contemporary of Vesalius—the insulting question were not asked, whether anatomy was of any use at all. The feeling of the masses was raised against the dissection of human bodies; and it is known that, at the commencement of the fourteenth century, the church for the first time gave permission for this to be done, but only under limitations which were still greater than those under which the larger number of our modern opponents would permit vivisection. It was no accident that the period of the reformation in the church first created for the great Vesalius a free field, so that he might test the truth of Galen's traditional dogmata by his own investigation of human bodies, and place true human anatomy in the stead of that anatomy of animals, which had during centuries formed the groundwork of all medical ideas on the internal arrangement of man.

And now, first of all, pathological anatomy—what obstacles it has had to overcome even in the present time! Nothing is more instructive in this respect than the narrative which Wepfer, the celebrated discoverer of the hæmorrhagic nature of ordinary apoplexy, gives of the acts of enmity with which he was persecuted when—it was towards the middle of the seventeenth century—the council of the town of Schaffhausen had allowed him to dissect the bodies of those dying in the hospital. The only reply which he made to those who said to him that it is injurious and disgraceful to soil his hands with blood and sanies, was, that he could cleanse his hands with some water; but that much more disgraceful and injurious is ignorance of anatomical facts, which inflicts on inexperienced physicians and surgeons a disgrace that not the Rhine, not the ocean itself can wash away.[1] Hence the study of anatomy is much rather to be praised, and to be supported by those who exercise the executive power in the State.

In fact, one Government after another has recognised the decided importance of anatomical science. As far as the civilised world extends, so far at the present day are human bodies dissected. Even the laity comprehends that, without the most accurate knowledge of the structure of the human body and of the changes which disease and recovery produce in it, skilled action on the part of the physician is impossible. Any one who can only take a general survey of the history of science, must know that both the greatest epochs of the resuscitation and reformation of medicine commenced with the definite establishment of both the principal branches of human anatomy, and were even essentially brought about thereby. In the sixteenth century it was physiological anatomy which brought about the definitive victory of empiricism over dogmatism, of science over tradition; in the eighteenth century it was pathological anatomy which replaced mysticism by realism, speculation by necropsy, obscure groping and guessing by systematic thought. The opponents indeed spoke of materialism; but Harvey has rightly said: "Sicut sanorum et boni habitas corporum dissectio plurimum ad philosophiam et rectam physiologiam facet, ita corporum morbosorum et cacheticorum inspectio potissimum ad pathologiam philosophicam.[1]

Antiquity had only one time in which a powerful effort was made for the independent development of human anatomy. It was the time of the Alexandrian School, in the third century B.C., when Erasistratus and his companions, under the protection of the Ptolemies, undertook the first regular dissections of human bodies. The school existed only a short time, and yet it caused the first perceptible agitation of the humoral system of pathology. With the more accurate knowledge of the arrangement of the nerves there grew up a new and more powerful generation of solidists; the empirics raised themselves against the dogmatists, and, though again soon enough subdued, they left behind them as a lasting inheritance the consideration that there is a certain limit to human piety, that the right of the individual to the preservation of the integrity of his body is interrupted by death, and that the veil which covers the mystery of life cannot be raised without the forcible destruction of the connection of the several parts of the body. It is this thought which, as finally realised, has brought forth modern medicine. But, eighteen centuries after the Alexandrian School, the impress of the humoral system of pathology still held independent sway in medicine. Of any positive progress in pathology during that long period nothing can be said. For Bacon has excellently said, in his "Novum Organum," "Quæ in Naturâ fundata sunt, crescunt et augentur: quæ autem in opinione, variantur, non augentur." The old humoral pathology was incapable of development, because it was not founded on nature, but on dogmata. From however different origins they had sprung, Galenism combined everywhere with orthodoxy: among the Arabians with Islam, in the west with Christianity; and it required the powerful movement of the Reformation to burst the chains within which antiquated custom and hierarchical schooling had fettered the thoughts even of physicians. From Erasistratus to Vesalius, and at last to Morgagni, is such an immense stride that it cannot remain concealed even from the weakest eye. Not only the outer form, but the whole nature of medicine has been thereby changed. If one follows Vesalius, yea, even Morgagni, in speaking of the humoral pathology as among still-existing things; if I myself am yet obliged to contend against Rokitansky, the last of the pronounced humoral pathologists, it must still not be forgotten that that was no longer the humoral pathology of Galen or Hippocrates. The four "cardinal juices" Paracelsus had already buried; modern medicine recognises only the actual juices which flow in the vessels, and thence penetrate into the tissues. This modern humoral pathology was essentially blood-pathology (hæmatopathology). In name only does it agree with the humoral pathology of the ancients: in reality, it is quite another thing.

But even hæmatopathology is now happily overcome, and indeed, again, through a proper direction of anatomical study. Since the first but very uncertain researches in the territory of so-called general or philosophical anatomy which Bichat began in the commencement of the present century, down to the more and more rapid advances which the present time has made by means of the microscope, in the knowledge of the more minute processes of healthy and diseased life, attention has been constantly more and more turned from the coarser relations of whole regions and organs of the body to the tissues of which those organs are constituted, and to the elements which again are the efficient centres of activity within those tissues. Immediately after Schwann had demonstrated the importance of cells in the development of the tissues, Johannes Müller and John Goodsir made the happiest applications of the new view to pathological processes; and, looking back to a period in which we ourselves have lived, and which embraces little more than a generation of man, we may now say that never before was there a time when a similarly great zeal in research, and a comparable—though only approximately so—progress in science and knowledge, has

[1] Joh. Jac. Wepfer. "Observ. Anat. ex Cadaveribus eorum quos sustulit Apoplexia." Schaffhausii 1658. "Præfatio: Turpior et damnosior rerum anatomicarum ignorantia est, quæ imperitis Medicis et Chirurgis ignominiam parit, quam nec Rhenus, nec Oceanus abluere potest."

[1] "Guil. Harveji Exercit. Anat." ii., "De Motu Cordis et Sanguinis Circulatione." Roterodami, 1671, p. 174.

spread among physicians. The multiplication of the powers of labour, the constantly increasing emulation in researches, the unmistakable increase in the depth of the questions proposed—all these are phenomena of the most gratifying nature; and one would be very ungrateful if he would not acknowledge that these were in a considerable measure to be ascribed to the improvements in the means of instruction and to the multiplication of laboratories.

No one can be more disposed to concede the high value of anatomical studies to the development of medicine, than one who has made it a part of the task of his life to place anatomy and histology in that commanding position in the recognition of his contemporaries which they deserve. Nothing lies further from me than to discourage those who still expect the greatest benefit to the practice of medicine to arise from following out these studies. May indeed the growing youth, who will have to follow us in assuring the progress of medicine, learn from our example how useful it is to lay the true foundation of our science in anatomy. Assuredly much of that which remains dark to us will then be rendered clear.

But we must not allow ourselves to be forced back on this way as the only permissible one. Were the attempt to hinder totally or in great part researches on living animals to become successful, the same procedure which has been now entered on against vivisection would also be commenced against mortisection. There would no longer be societies for the protection of animals, which we see opposed to us, but societies for the protection of human bodies. There would no longer be thunderings against the tormentings of animals, but against the desecration of corpses. Under the standard of humanity, which is just now unfurled even for animals, there would be preached in a still more impressive manner the campaign against the barbarity of medical men. People would appeal to the feeling of the masses—to the mother on behalf of the body of her child, the son on behalf of the dear remains of his parents. It would be proved that the dismembering of human bodies is injurious to morals and opposed to Christianity. It would be shown that the anatomy of man is useless for the treatment of disease; and perhaps there would be found ignorant or timid or egotistical medical men who would come forth as witnesses against science. The mildest of our opponents would perhaps propose to us the compromise that we should again make the dissection of animals the foundation of instruction. In short, we should be thrown back to the time before Mondini, before Erasistratus.

Such thoughts are by no means the productions of an alarmed fancy. The study of history teaches us sufficiently that victorious fanaticism knows no limits. It desires to heap to the full the measure of its victories; and, even when the traders are contented, the irritated masses press on to obtain the whole results. It is indeed not at all necessary for us to go back to antiquity in order to bring before our eyes the condition of such minds. In no country of modern time are there wanting examples which are recognisable by the eye; for, along with the societies against "scientific tormentors of animals," there exist everywhere, but mostly in a more unassuming form, brotherhoods and associations of all kinds which labour most zealously against the scientific examination of dead bodies. It needs only an impassioned and exciting agitation, such as is now going on against the "torture chambers of science," to denounce to popular indignation the dissecting-rooms as places where the youths under instruction are made barbarous. Whoever undertakes, with the same extravagant fancy as is now used in delineating the physiological laboratory, to describe the *post-mortem* examination of a man, or an anatomical theatre, will not fail to have readers who will turn away with horror and amazement at the misdeeds of anatomists.

In vain will an appeal be made to the fact that not one single school of medicine has existed which has, without a fundamental knowledge of anatomy, established lasting advances in the science or the art of healing. The homœopaths and the so-called nature-doctors (*Naturärzte*), who indeed are already on the scene to strengthen the ranks of the anti vivisectors, will step forth and praise their results. Scepticism, which, from time to time grasps about even in medical circles, and which only too easily finds there followers who have in vain called on medical aid for themselves or their belongings—it will scornfully point out how often the physician is powerless against disease. Therapeutics will be thrown aside as useless lumber; and it will be pointed out to us, as is now already done in the petitions of the societies for the protection of animals, that therapy is to be replaced by hygiene, the treatment of individual patients by general measures of public sanitation. And the attempt will then be made to excite the belief that prophylaxis can exist without anatomy or experiments on animals.

In so large an assembly of medical men as this is, a glance at these present teaches in how many special directions the medicine of to-day has gone. Not every one of these directions is in like measure and as constantly in want of all the means of inquiry and scientific preparation, which are indispensable to cure disease as a whole. Hence, from time to time, a perceptible one-sidedness becomes manifest in certain of these special arrangements. One believes in his own sufficiency, and looks with indifference, sometimes with a kind of polite contempt, on the rest of medicine. Even the truly scientific studies are not exempt from such one-sidedness; on the contrary, human pride, the tendency to over-estimation of oneself, prevail more readily in these than in partial disciplines. We ourselves have seen that organic chemistry, by a most partial use of a very moderate store of knowledge, has made the attempt—and indeed not without some temporary result—to prescribe its laws to medicine; and that numerous practical physicians, unmindful of the history of our science, have in fact sought safety in a new kind of iatrochemistry. Yes, I have a very lively remembrance of the fact that, when I myself was entering on the scientific career, the hope of giving a purely physical aspect to biology was so powerful, that every attempt at morphological study was treated as something antiquated.

We have not allowed ourselves to be prevented by this from carrying on anatomical research with every exertion; and we are now in the happy position of seeing it everywhere acknowledged, that every advance in minute anatomy sees behind it an advance in physiological knowledge. Physiologists themselves are more and more becoming also histologists. No one however must say that physiology is becoming totally dissolved in histology. No attempt must be made to replace one special subject by another. What is necessary to all branches of medical science in general is the *knowledge of life*. But this can as little be attained by a simple external examination of the living as by a partial investigation of the dead. It can be reached by no single study or specialty; it is much rather the collective result of the cultivation of all individual branches of science.

What is to be attained by a mere external examination of the living body has been thoroughly taught by the older medicine. For centuries sick and healthy have been observed with assiduous diligence, and in fact most valuable material has been collected in the most ingenious manner; but, on the whole, no advance has been made beyond "symptoms." What was perceived were the signs of something internal which was not perceived—indeed the possible perception of which was hitherto doubted. Life itself stood as it were outside observation; it was only a subject of speculation. Intellectual formulæ were laid down, spiritualistic or materialistic, according to the general tendency of the mind of the individual or of the time; but all agreed in the conviction, that life itself is a transcendental and metaphysical problem. For the practical physician, knowledge that was founded in fact began with symptomatology; for disease as such was apparently not less transcendental than life itself, whose antitype it constituted.

How has it now come to pass, that symptomatology has entirely lost the high position in which it still stood little less than a generation ago, to such an extent that in most universities it is no more taught as a specialty? Have symptoms no more any importance for the physician? Can a diagnosis be made without a knowledge of symptoms? Certainly not. But, for the scientific physician, the symptoms are no more the expression of a hidden power, recognisable only in its outer workings: he searches for this power itself, and endeavours to find where it is seated, in the hope of exploring even the nature of its seat. Hence, the first question of the pathologist and of the biologist in general is, Where? That is the anatomical question. No matter whether we endeavour to ascertain the place of the disease or of life with the anatomical knife, or only with the eye or the hand; whether we dissect or only observe, the method of investigation is always anatomical. For this reason, the thoroughly logical founder of pathological anatomy named his fundamental book "De Sedibus Morborum"; and hence this book became the starting-point of a movement which, in a few decades, has changed the entire aspect of science.

This change has been carried out to the greatest extent in ophthalmic surgery. Who could limit himself to perceiving

that modern ophthalmology has scarcely a single point of similarity with that of the last century? Who contents himself with the symptom of amaurosis? Who despairs of recognising in it the existence of glaucoma? Every ophthalmic surgeon has in his hands the means of studying the thing itself, and not merely its signs. Even the anti-vivi-sectors acknowledge that ophthalmology is a study that is capable of effecting something. But they forget that every organ of the body is not so favourably placed and arranged for the observation of its inner processes as is the eyeball. Since the wonderful discovery of the ophthalmoscope, anatomical analysis, even without the use of the knife, has become capable of penetrating so far into the individually remote, that we can immediately observe and study by themselves the smallest features of the fundus oculi, even, indeed, its single cells, or groups of cells, just as in an artificial preparation of an eye that has been excised. But it must not be forgotten that long anatomical and physiological studies have been a necessary preliminary to the interpretation of that which is now so easily perceived. The structure, arrangement, and function of each single part had first to be laboriously established before it was possible, by a transitory glance at the altered tissue, to recognise what is especially changed; and no medical man will attain to a true comprehension of the essence of these changes if he have not previously learned to recognise most accurately the anatomical and physiological nature and the possible pathological changes of the individual constituent parts of the eye.

They speak lightly who object to us, that not all the branches of medicine stand on the same height with ophthalmology. That will never be the case. Just as it is easier to explore the sea in its depths than the solid land, so will the most transparent organ of the body always be the most convenient place for medical diagnosis and treatment. While it is possible to observe without difficulty a cysticercus in the hinder part of the retina, one will always be taught to bring a cysticercus of muscle or a trichina in a patient to light by vivisection. Never can it be required that every medical specialty should altogether equal ophthalmology in security of treatment and diagnosis; but any measure of success can only be sought in the use of the ophthalmological method in a corresponding manner in the other special departments. This method, however, is anatomical, or, as it has otherwise been expressed, localising.

With this, we have reached the point which denotes the boundary between ancient and modern medicine. *The principle of modern medicine is localisation.* To those who still constantly ask of what use modern science has been to practical medicine, we can simply point out that every branch of medical practice has accommodated itself to the principle of localisation, not only in pathology, but also in therapeutics, and that thereby the greatest benefit has accrued to the sick. It is quite superfluous to seek out single examples in order to show what profit the new knowledge has brought. Such examples are abundant. But we do not require them, for we can point to the general character of modern medicine. All those studies which already at an earlier period had a natural tendency to localisation, such as special surgery and dermatology, have in this way been raised to their present state of perfection. Those, however, which have retained from the old humoral pathology a tendency to the establishment of generalising formulæ gradually renounce the favourite tradition; and the fact is more and more comprehended, that generalisation in truth is nothing else than *multiplication of foci*, and that the cure of a so-called general disease signifies just as much as the eradication of a single focus. That was in fact a reform in head and limbs; and he who has not grasped it ought not to say that he has consciously followed the progress of science.

The notion of the general validity of the doctrine of the localisation of disease and of the multiplication of foci of disease in the same individual, stands, as was often objected to me in the beginning of my career as a teacher, in strict opposition to the idea of the *unity of disease*, or, as it is expressed in customary language, to the *ens morbi*. My former colleagues still retained large portions of this idea; they believed that the practical physician entered into arbitrary, and therefore dangerous, speculations, when, in the presence of a single case of disease, he assumed the disease to be a plurality. To me it seems rather the reverse; that the physician enters on a fruitless project (*schematismus*), and one dangerous to his patients, if he suppose each individual case of disease to correspond to the opinion of his school or his own private view, and calculate his prognosis and treatment thereby. Meanwhile, these considerations, derived from medical practice, on the *utility* of a certain way of perceiving disease, can lead to no decision as to its *truth*, and yet, at this result only is it possible to arrive. How shall we establish it?

All the world is at one on this point, that disease presupposes life. In a dead body there is no disease. With death, life and disease disappear simultaneously. This consideration led the older physicians to assume disease to be a self-living or even animated essence, which took its place in the body along with the vital principle. Many went so far as to define disease as a combat between two contending principles, the innate life and an intrusive foreign body. But all came back to life as a preliminary condition of disease. The view was first lost in the old Leyden school; from Boerhaave emanated the dogma, which his pupil Gaubius placed at the head of his long-used "Handbook of General Pathology," the first written on the subject: *Morbus est vita præter naturam.* Disease is life itself; or, to speak more correctly, it is a portion of life.

This assumption displaced the unfortunate dualism which had so long dominated medicine; or, at least, it ought to have displaced this dualism between life and disease. If, nevertheless, it has not completely done this, and if more than a century has been required to break up the still constantly existing dissonance, the reason lies in the difficulty of finding a satisfactory conception of life. And here the question must not be passed by, Where has life its special seat? *Ubi sedes vitæ?* John Hunter went back to the ancient view, already expressed in the Mosaic formula: "The life of the body is in its blood." Flourens believed that he had found the seat of life, the *nœud vital*, in the central nervous system, in the medulla oblongata. The one, like the other, found himself obliged to institute experiments on living animals for the investigation of this difficult question. Therewith the experimental method in the more strict sense began to pass into the practice of pathologists. Vivisection became a regular aid to research.

Certainly the consideration that a knowledge of life can only be obtained on the living being was long present. Beyond doubt it was already formed in antiquity. But it is difficult to determine with accuracy the time when it first became practically active. Uncertain statements only on the subject are available. Zacharias Sylvius, a physician of Rotterdam, who wrote the preface to the Dutch edition of Harvey's "Exercitationes," calls to mind the tale of Democritus, whom the Abderites regarded as insane, because they saw him constantly engaged in vivisection; when however the great Hippocrates was sent for to cure him, he fully recognised the value of his proceedings, and declared that all the Abderites were lunatics, and that Democritus alone was sane.[1] Probably this story has been narrated at the expense of the good Abderites; but it still shows that vivisection already "lay in the air." I will not attempt to decide whether it is true that the teachers in the Alexandrian school actually availed themselves of the permission of their king to dissect criminals. The only conclusion which I can derive from these tales is that researches on animals must surely have at that time been already practised. For whoever reflects on the vivisection of men must acknowledge that, especially at a time when the anatomy of animals formed the foundation of medical study, vivisection had certainly been previously done on animals. In the school of the empirics which proceeded from that of Alexandria, and in which necropsy was taught as the chief means of knowledge, experiment also appears as having a recognised claim; in the celebrated formula, which has been called the tripod of the empirics, and which served as the programme of their school, deliberately-planned experiment is expressly mentioned (φυσικὴ ἢ αὐτοσχεδίη τήρησις). Only it is not evident to what extent this research on living animals was carried on. Hence it is also unprofitable to inquire what advantage of any kind ancient medicine derived from vivisection.

In fact, the first great and distinctive example of successful vivisection which the history of medicine knows is that of William Harvey. The foundation of the doctrine of the circulation, which in the main was experimental, has radically changed the whole direction of the thoughts of physicians.

[1] "Harveji Exercit. Anat." Roterod., 1671. "Præfatio": Democritus solertissimus operum naturæ perscrutator, cum assidue secandis animalibus occuparetur, existimatus fuit insanus ab Abderitis; qui miserati sortem hominis advocarunt Hippocratem, ut illi medicinam faceret mentemque alienatam restitueret. Rogatus decurrit et offendit Democritum animalia secantem, quo spectaculo mirum in modum oblectatus, omnes Abderitas insanire pronuntiavit, solum sapere Democritum."

Had we this one example alone it would be sufficient to prove brilliantly the utility, yea, the indispensability, of vivisection. Never has a dogma firmly established by the tradition of centuries and every kind of authority, which in truth formed the central point of a powerful and generally acknowledged system, been annihilated with such a headlong downfall. In complete recognition of the importance of such a man, Albert von Haller said that Harvey's name was the second in medicine, that of Hippocrates being the first. But it was a difficult step, to advance a new and unheard-of doctrine which interfered with science in so revolutionary a manner. Having hesitated long whether he should publish his discovery, and when he at last carried his resolution into effect, the great vivisector cried: "Utcumque sit, jam jacta est alea, spes mea in amantium veritatis et doctorum animorum candore sita" (*loc. cit.* p. 81).

It is certainly due, even in the present day, to the purity of a truth-loving and cultivated mind, to exonerate Harvey from the reproach of heartlessness, perhaps of brutality, of which our anti-vivisectionists are so liberal. His new knowledge had cost the lives of many animals; he started, as he himself says, "ex vivorum (experiendi causâ) dissectione, arteriarium apertione disquisitionæque multimoda." And yet that was the least thing with which he was reproached; even kings at that time were so little tender-hearted, or, I may say, with an opponent, were so brutalised, that King Charles I. found pleasure in seeing the experiments of his body-physician.

On the other hand, after Malpighi had, still in the same century, demonstrated the flow of blood in the capillaries of living animals, and after our century has added the knowledge of the existence of an actual capillary wall, the doctrine of the circulation appears so self-evident, it has so thoroughly entered into the ideas of all, that it already requires a peculiarly-trained mind to comprehend the opinion of the older physicians on the local relations of the current of the blood. Whoever goes unprepared to the study of the medical classics, falls from one misunderstanding into another. The ideas of the nature of local processes are entirely changed, and yet the circulation, the capillary certainly more than that of the larger vessels, stands in the foreground of pathological interest almost more than in truth it should. The widely comprehensive doctrine of inflammation and new growth, within which nearly the greater part of practical cases occur, was founded on experiments on the capillary circulation; not less so was the doctrine of the cure of local diseased processes of most varied kinds.

Even the worst opponents of vivisection recognise Harvey's services. But, say they, since then, nothing more of importance has been accomplished by vivisection. They do not know that it is precisely that department of the doctrine of the process of the circulation which embraces the vital properties of the organs of circulation, which is entirely unmentioned by Harvey.

On what does the activity of the heart depend? What influence do the vessels exert on the propulsion and distribution of the blood? What share falls to the arteries, what to the veins, what to the capillaries? All these questions are of the highest practical importance, and none of them can be investigated otherwise than by experiments on animals. But Harvey could not attack these questions, because in his time minute anatomy was not yet developed. Who knew anything of the nerves of the heart, or of the vessels? Who had any notion as to the participation in the manifestations of the action of the heart and blood-vessels, on the part of the nerves, which supply the parietal structures, especially the fine muscles?

An interval of two centuries again intervened before Edward Weber, by experiment on the vagus nerve in a living animal, first revealed the mystery of the innervation of the heart; and this, again, in a quite unexpected and unprecedented manner; and before our now so much abused friend Claude Bernard likewise showed on a living animal the influence of the sympathetic nerve on the vessels of the head and neck.

Now for the first time, and through numerous other experiments which have tended to this end, we understand the circulation in its special characters. The pulse, that so highly treasured object of the old symptomatology, allows itself to be interpreted. It is to us no longer the sign of this or that disease, but the sign of the existence or non-existence of certain activities, of strength or weakness, of irritation or relaxation of certain tissues. Now for the first time we can understand in its individual peculiarities the action of the heart itself and the operation on it of certain substances—*e.g.* cardiac poisons; and it is not almost alone the department or diseases of the valves, to which alone, and with a scorn that cannot be rightly understood, the anti-vivisectors point on account of their incurability, but also the department of febrile diseases, which we are in a position to survey as well with regard to their symptoms as to their nature and their results.

The length of the interval of time between Harvey and the more recent experimenters on the innervation of the vascular apparatus is explained by the circumstance that in that intermediate time two entirely new studies had to be created, to both of which the discovery of the circulation was an impulse and a preliminary condition. I mean physiology and general pathology; thus, indeed, both these studies, which are to be regarded as the chief support of the experimental method, and which it was originally the custom to comprise under the name of "Institutiones Medicæ." Hermann Boerhaave had, in his professorship, combined them, and, indeed, had even united them with practical medicine; under his pupils the division of labour commenced, and the formal separation of the studies. Haller was the special creator of physiology. His experiments went first in the direction of exploring the vital properties of individual parts of the body, of single tissues, as would now be said. Among these properties, following the distinguished Glisson, a man, it seems to me, not even now sufficiently honoured in his country, he assigned a prominent place to irritability. It would lead me too far if I in this place desired to attempt to show forth individually these memorable researches, the comprehension of which was rendered extremely difficult by the then not yet sufficiently complete explanation of the motions "irritability" and "contractility." For our purpose it is sufficient to point out that here for the first time nerve and muscle, the two most highly developed and thereby most energetic portions of the animal body, were made the subjects of experiment with regard to their special forms of activity. Contraction and sensibility appear as the special signs of living activity. Therewith the question of the basis of living activity was so nearly approached that Gaubius, who at the same time laid the foundations of general pathology, indicated the vital force as the source of contraction, without going further.[1]

From these beginnings was developed, at first in a very obscure and equally unprofitable manner, especially clouded by speculative vitalism, the doctrine of life in its modern form. It has required much longer labours, mostly experimental, to arrive at a great and practical result in spite of all deviations. From the conception of irritability, originally created by Glisson, that of contractility has gradually become separate: and the contrast in which Haller placed irritability and sensibility with regard to each other has been dissolved, by the fact that contractility and sensibility are regarded as two special forms of expression of life connected with various elements, and are subordinated to irritability as the general expression. In this sense, irritability and vitality are nearly identical. Both are properties of tissue, and as such directly or indirectly accessible to treatment and experiment.

In fact, experimentation is now rather directed to the tissue itself. Galvani's discovery of electric contractions, the labours of Alexander von Humboldt on irritated muscle and nerve-fibre, and many other contemporaneous researches, afford evidence of the changed direction in which the new biology laboured. More and more sank down the mysticism of the spirits of life and of disease, the speculation as to an individual vital force; and from generation to generation medicine assumed more and more the character of a real natural science. The obscurity which had dominated especially the nervous system, disappeared under the common labours of anatomists and experimenters; and especially since Charles Bell taught the difference of the nerves hitherto considered as similar in nature, and thereby opened the road to research on the special importance and power of the single divisions of the central nervous system, one work after another has appeared, which has diffused new light on this difficult and complicated subject. It is impossible to go through all these works on this occasion, and it would be superfluous in an assembly of such accomplished men, many of whom have themselves laboured in this glorious work.

I will now only briefly point out that among these labours a constantly clearer and more triumphant idea has advanced, which in its beginnings reaches far back into past time—namely, the idea of the proper life (*vita propria*) of the tissues. Every new form of experiment which is devised renders new parts accessible

[1] Gaubius, "Institut. Path. Med.," p. 71. "Vis vitalis solidi est, qua illud ad contactum irritamenti se contrahit."

to scientific examination, and with each step in advance we become more clearly convinced that life, regarded as a great unit in the established sense, is a pure fiction, arising from the observation that in the hierarchical organisation of the human body certain organs attain so elaborate a structure, and therewith so great importance, that they with complete right merit the name of vital organs. And as among these organs the *medulla oblongata* possesses the greatest importance, it is easily comprehensible that the idea should arise that it might really be the seat of life. But we know now that life is a collective functional action of all parts of the higher or vital, as well as of the lower and less important; and that there is no one seat of life, but that every true elementary part, especially every cell, is a seat of life. In biological research, also, as well as in pathological, we have arrived at a multiplication of foci. Of course the number of vital foci is much greater than that of foci of disease can ever be; and hence disease and life, or to speak more accurately, diseased and healthy life, can very well coexist in the same organism; always, however, so that disease signifies a reduction, a *minus* of healthy life. By this research we have even rediscovered the long-lost essence of disease, not indeed in a spiritualistic form, but as a quite material *ens*, a genuine incarnate thing—*the altered cell*.

Has all now produced advantage? Was it worth the trouble to inflict pain on so many animals? to kill so many animals? Is there a really justifiable claim for allowing the experimental method to proceed still further? We can answer all these questions confidently in the affirmative. Not every experiment on animals has results as great as that of Galvani, results which have not merely led to a new and effective method of treating disease—electrotherapy; which have not only disclosed a large new territory of vital processes, but have supplied the first preliminary condition for an incalculable number of the most important technical arrangements, the knowledge of the natural course of events. But galvanism might yet appear to limited and timid heads as an instructive and refreshing play, for the reason that not every result of true observation of nature is usually brought forward at once, and that nevertheless it may be of the highest practical value. The cellular theory and the proof of the *vita propria seu cellularis* are in themselves very abstruse things, and no one can cure patients by their means without understanding something further. And yet they have become the foundation, yea, in a certain measure the security, for localising therapeutics, and they will surely become more so from day to day, when first materia medica in its wider extent shall have gone on the way which toxicology has already for a long time followed in a manner so rich in results.

How then can a great result to the science of healing be expected, if research in animals be cut off? For a long time no remedy has been more rapidly recognised, or more extensively used, than chloral, the effects of which were discovered and established experimentally by Herr O. Liebreich in my laboratory. How would it have been possible to know how to ascertain those effects without experiments on animals? The animals' friends say to us, "Then try the new medicine on yourselves!" They refer us to the provings of medicines by the homœopaths. But, quite independently of the fact that the provings of the homœopaths have not taught us to recognise one single new remedy which can be compared even at a distance with chloral, and that these provings, even in regard to already known remedies, do not in the least correspond to scientific investigations; that thus they cannot be altogether regarded as an original example—one will yet not be able to earnestly desire that very different, possibly poisonous bodies, should be made the subject of self-experimentation by physicians or other men. This kind of morality, which forbids experiments on animals and counsels experiments on one's own life or on sick men, misses, in fact, the first foundations of intelligent examination.

The proof of the great importance of hygiene and prophylaxis is rather superfluous. If any class of men has been active in this direction it is surely medical men. Never has there been a want of zealous hygienists among them; and when a great problem of prophylaxis was to be solved, one might be sure of finding medical men engaged in the work. We are so accustomed to this obligation that we always regard hygiene and prophylaxis as belonging to medicine, and to no other science. But it is empty talk when it is said that prophylaxis will render therapeutics—yea, even in a certain degree, medicine—superfluous. The arrangement of this imperfect world is such that there surely will be sick as long as men exist; and we are not afraid because of the threat that there will be no further need of us. Not even through the assistance of hygiene will people be able to do without us; and still less without experiment on animals. Will even the hygienists be condemned to test the various "causes" cold and warmth, dryness and moisture, dust and noxious gases, micrococci and bacteria, on their own persons, in order that they may from such self-observations determine their effects, and formulate laws? Intelligent Governments will comprehend that it would be an act of madness to sacrifice human life, merely because it occurs to a small number of persons that it is criminal to sacrifice the lives of animals. Medical men are already more exposed in epidemics of all kinds, in the performance of their duties in hospitals, in the country, in their nocturnal visits to the sick, in operations and necropsies, than any other class of the community as a rule; and it requires all the blindness of the animal fanatics to require also of them that they should test on their own bodies the remedial, or poisonous, or indifferent action of unknown substances, or that they should determine the limit of permissible doses by observations made on themselves.

In the name of humanity, of morality, of religion, the suppression of experiment on animals is demanded. For, in fact, it is not merely vivisection that is in question, but experiment on animals; that is, the experimental method in general. When the term vivisection is used it is made to include in like manner all painful actions in which there is no cutting; indeed, to prevent any misconception, not only physiological, but also pathological and pharmacological, experiments, are expressly included. *The criterion is pain. Everything by which, in the way of experiment, pain is inflicted on an animal is torture of animals*, and so far immoral, and contrary to religion. With this definition of torture of animals it might be possible to arrive at exceptional results by applying it to other callings or men. The dog-fanciers, who in the rearing of their dogs often use, or cause to be used, methods full of torture and painful chastisement, would readily come into great danger. The improvement of horses for certain purposes would have to be entirely put down. A great part of our domestic animals would have to remain untrained, so that pain might be spared to them. We should perhaps arrive at conditions similar to those produced by the wild dogs in Turkey.

Individual anti-vivisectors are at least so far consistent that they would see the slaughter of animals also forbidden. From the vegetarian standpoint, the opposition gains a kind of systematic aspect. Thus Herr von Seefeld[1] demands a vegetable diet and the prohibition of vivisectors; but as he, as a vegetarian, has no need of flesh, he is strongly inclined to make still further concessions. Thus he rejects hunting for the purpose of pleasure, but cannot altogether dispense with it as a means of defending life. Others go still further, and sacrifice also war. The principle can scarcely be denied, that death is worse than torture. There could scarcely be a criminal code, which punishes the premeditated killing of a man less severely than the torture of a man. Not without reason is it alleged that a man who still remains alive after his misdeeds may recover and attain to a complete or entire enjoyment of life. Grounds of mitigation in cases of murder and manslaughter are allowed also to men; but, as a foundation, the extremest injury which can be inflicted on man is always and everywhere the most severely punished.

As regards animals, the anti-vivisectors, on the contrary, consider torture to be worse than death. Although they reject every torturing or painful method of death, even for cattle, they without the slightest consideration cause animals, even highly organised ones, to be slaughtered or killed, not only for eating, but also for other purely subjective reasons. They go, indeed, so far as to demand that an animal which has survived vivisection shall be killed, although it might possibly still enjoy a long and happy life. Is there any logic in this, or any morality? How? May we have the right to kill an animal on any ground of public utility, to eat its flesh, to sell its skin, to pound its bones to manure for the field? and are we not to have the right of subjecting it to scientific research, which we institute on entirely ideal grounds, or on the grounds of the public weal, in which we even perhaps run the risk of becoming diseased? It will be difficult to assume that we institute researches on glanders or splenic fever for pleasure, or to pass away time, or without knowledge of the great danger of inoculation. Whoever allows himself the right to kill animals, has no right to forbid physi-

[1] Alfred von Seefeld. "Altes und Neues über die vegetarianische Lebensweise." (Hanover, 1880.)

cians to vivisect animals for experimental purposes, or to undertake painful operations of any other kind.

Of course we cannot desire that the misuse of this right should escape punishment. For it is with such an abuse, not with the production of pain, that torture of animals first comes into operation. Were every production of pain in itself an act of torture, punishment ought to be inflicted on a veterinary surgeon when he operates on a sick horse for the purpose of curing it. Culpable torture of animals lies before us, when pain is inflicted on an animal in a useless manner, and without purpose. Hence nothing can be said against the view that every experimenter should be subject to official inspection; but surely this does not require a society for the protection of animals. He who has a greater interest in domestic animals than in science, that is, in the knowledge of truth, is not qualified to be an official controller of scientific affairs. To what would it lead, if an experimenter, who had commenced his experiment in good faith, had perhaps to answer to some layman during the experiment, or to a magistrate afterwards, the charge that he had not selected some other method, or some other instruments, or perhaps some other experiment?

No: here is no question of objective right. So long as perfect liberty is left to every possessor of animals to kill his animals, be they wild or tame, at any time, and according to his own judgment, so long must it also be permitted that, for scientific ends, and thus on purely internal grounds, experiments should be made on living animals. But the necessity of such experiments can naturally only be decided by the inquirer himself; as to the choice of place, time, the admission of strangers, he may be required to communicate with the inspector; but the carrying out of the experiment must remain in his own hands. So we understand the expression of the freedom of science.

What is objected to us is, that it is the outraged feelings of the possessor of horses, pet dogs, and parlour cats that excite him to the belief that the same thing may happen to his beloved animals as to the animals in the learned institute. We can sympathise with him. We would force no one to deliver to us his favourites, nor would we steal them. Were either of the two to occur, probably in every country the intervention of the magistrate would be called on with effect. But we also require that the disposal of the life and maintenance of those animals which have come into our possession in a legitimate way, should not be lessened to us, and that we should not be considered or declared to be *à priori* rough, void of moral feeling, and barbarians standing almost on the threshold of crime. The evidence that moral earnestness is failing in modern medical circles is nowhere afforded. The reproach that Christianity is imperilled by vivisection is worthy of Abdera. The assertion that the medical youth are inevitably "brutalised" by dissection and vivisection is, as usual, snatched from the air; as it is also a calumny that the vivisecting teachers have suffered injury to their morality.

At least however there is no ground to fear for science itself. To it is applicable what Bacon said of the sun: "Palatia et cloacas ingreditur, neque tamen polluitur."

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 1.—M. Jamin in the chair.—The following papers were read:—On the formation of tails of comets (second note), by M. Faye. Herschel, Arago, Delaunay, and other astronomers did not thoroughly study the tails of comets, but Newton had already given a quite sufficient explanation of the phenomena. The tail is nothing else—he maintained—than the result of a continual emission of molecules from the head of the comet. It is very much like the tail of smoke emitted by a running locomotive, its outer end being lost in space, and the inner one continually receiving a new supply of molecules. M. Roche, who has made the necessary calculations, taking account of the repulsive force M. Faye advocates, has worked out all those shapes of tails which we witness in reality.—On the equivalence of quadratic forms, by M. Jordan.—On a modification of the electric lamp, by M. Jamin, being the result of observations on the electric light in vacuum, and in closed vessels containing various gases.—On the perchloric acids, by M. Berthelot.—On the travels of Moncatch-Apé, by M. Quatrefages. This American Indian undertook a journey to the north-western coasts of America at the beginning of last century, in search of the origin of his race; whilst on this coast he learned and witnessed that it was visited every year by white men with long black beards, and M. Quatrefages proves that these men were originally from the Loo-Choo islands.—On the first meteorological, topographical, and hydrographical observations at the future Panama canal, by M. de Lesseps. Several maps of the coast are prepared, and a meteorological station is opened at Colon.—On the application of electromotive power and of M. Planté's secondary piles to the direction of aëro-tats, by M. Tissandier. In an aëro-tat which has a volume of 2200 litres, 3·50m. long, with a diameter of 1·30m., and can raise a weight of 2 kilogrammes, having a Siemens machine which weighs 220 grammes, and a secondary couple of 1300 grammes, the propulsory helix makes six and a half revolutions per second, and the balloon acquires a speed of 1 metre per second for forty minutes. The small Siemens machine, with three elements, produces the work of 1 kilogrammetre.—The elements of comet *c* of 1881 (Schäberle), by M. Bigourdan, as deduced from observations at Vienna on July 18, and at Paris on July 23 and 28. Its brightness, which is still increasing, will be on August 23 seventeen times as much as it was on July 18.—Spectroscopical observations on the comets *b* and *c*, 1881, by MM. Thollon and Tacchini.—On the lengths of spectral bands given by compounds of carbon, by M. Thollon.—On the constitution of comets, by M. Prazmowski.—On the theory of trilinear forms, by M. Le Paige.—On the influence of pressure on dissociation, by M. Lemoine.—On the heat of formation of explosives, by MM. Sarrau and Vieille.—On oxycyanides of lead, cadmium, and mercury, by M. Joannis.—On the heat of combustion of heptane and of hexahydrotoluene, by M. Louguinine.—Third note on the magnesia industry, by M. Schlösing.—A contribution to the study of the transmission of tuberculosis, by M. Toussaint. The juices of animals which have had tuberculosis transmit the disease with very great ease, even when submitted to a high temperature, but especially when employed uncooked.—On the injection of the virus of rabies into the circulation, by M. Galtier. It seems to prevent infection.—On hemeralopia and on the functions of the visual purple, by M. Parinaud.—On the applications of electromotors, by M. Trouvé.

VIENNA

Imperial Academy of Sciences, July 21.—L. T. Fitzinger in the chair.—A. Rollett, on the derived albumins noted as acid-albumins and alkaline albuminates.—Dr. Stur, on the Silurian flora of the H-h_1 stratum in Bohemia.—S. Lustgarten, on an ethyl nitrate formed by the action of nitric acid on glycogen.—Ernst Lecher, on the spectral distribution of radiant heat.—Dr. T. Kessel, on the function of the external ear in relation to the space-perception.—On the difference of intensity of a linear-produced sound in different directions, by the same.—F. Fossek, on the products of condensation of isobutyl aldehyde.—Zd. H. Skraup, on quinine and quinidine.—Note on some quinine compounds, by the same.—Prof. Freund, on the formation and preparation of trimethene alcohol from glycerine.—Preliminary note on trimethene, by the same.—H. Weidel, on a compound isomeric to α-sulphocinchoninic acid.—G. Goldschmidt, on mono- and dinitropyrene and amidopyrene.—E. Weis, a communication on the third comet of the year 1881 (1881 *c*), discovered by Schäberle at Ann Arbor (Michigan).—T. Woehner, report on his observations of the earthquake phenomena in Croatia in the year 1880.

THE CENTRAL AFRICAN LAKES

To the Central African Lakes and Back: The Narrative of the Royal Geographical Society's East African Expedition, 1878–80. By Joseph Thomson, F.R.G.S. Two vols. (London: Sampson Low and Co., 1881.)

OUR readers must be familiar with the leading features of the remarkable Expedition which set out at the end of 1878 under the leadership of Mr. Keith Johnston, and returned in 1880 under that of Mr. Joseph Thomson. We have already told the story of the Expedition pretty fully, and Mr. Thomson himself described in these pages the main points in the geology of the Expedition which he traversed. Mr. Thomson was a very young and inexperienced man when, by the sad death of his accomplished chief, the command of the Expedition devolved upon him, just after it had got over the initial difficulties of the coast region and entered on the great tableland which occupies the greater part of the African area. Mr. Thomson showed himself at once equal to the emergency, and succeeded in winning a reputation that is likely to prove fruitful of good results both for himself and for African geology. He has been equally successful in telling the story of his journey. He writes in quiet and simple, but effective, style, his pages are full of incident and information of great interest, and he has a sense of humour and a love of fun which are not only of service to him under trying conditions, but which render his book light and pleasant reading. After seasoning themselves by a little trip to Usambarra, Messrs. Johnston and Thomson (the latter geologist to the Expedition), at the head of 150 men, left Dar-es-Salaam in May, 1879, for the north end of Lake Nyassa. A month later Mr. Johnston died at Behobeho, to the north of the Rufiji, just when the mountains that bound the plateau had been reached, through the usual difficulties attending African travel, partly arisIng from the nature of the country, partly from the natives, and partly from the men who formed the Expedition; but Mr. Thomson overcame them all with more than usual tact, and with unprecedented success. After a short rest at Lake Nyassa the route was resumed over the previously untraversed country between Nyassa and the south end of Lake Tanganyika. Leaving most of his men here, Mr. Thomson, with a small contingent, proceeded up the rugged west side of the lake to the famous river, about whose course Messrs. Cameron and Stanley gave such inconsistent accounts—the Lukuga. Mr. Thomson's observations on this river are of great value in connection with African hydrography. He found that Cameron and Stanley were both right. At Cameron's visit, what little current existed was towards the lake; Stanley, later on, found a distinct current setting from the lake, and prophesied that in a short time the barrier of vegetation across the river not far from its mouth would be carried away, and the Lukuga would carry the waters of Tanganyika in a full stream to the Lualaba-Congo. And this, Mr. Thomson found, had actually come to pass; he saw the Lukuga as a broad, swift effluent from Lake Tanganyika. When, however, he returned two months later, he found that the strength of the current had considerably decreased, as had also the volume of the river. Mr. Thomson discusses the interesting problem of the Tanganyika at some length, and with great intelligence, as well as with the knowledge of a trained and practical geologist. He refers to the facts observed by previous travellers as well as himself, as to the rise and fall of the level of the lake, the hydrography of the neighbouring country, &c., and concludes as follows:—

"With these facts before us the necessity of Tanganyika having a regular outlet is not so apparent as it seems to have been to Cameron. Neither need we, like Stanley, invoke the aid of great convulsions to account for the interruption or intermittency of the outflow. The phenomena are sufficiently accounted for by the facts I have enumerated, viz. (first), that since the Arabs settled at Ujiji till within the last five years there has been no very marked rise in the level of the lake; (second), that the rapid rise of the lake after that time was due to unusually wet seasons; (third), that the normal rainfall is less than fifty inches in the year; (fourth), that Tanganyika drains a remarkably small area of land, and has only a few insignificant rivers, torrents, and streams falling into it; and (fifth), that the volume of water passing out by the Lukuga is diminishing so rapidly as to be markedly noticeable in two months, even in the course of the rainy season, so that quite possibly the next traveller may arrive to find little or no water leaving the lake. These considerations, then, as well as all my inquiries and observations, lead me to conclude (first), that under normal circumstances the rainfall and evaporation nearly balance each other; (second), that many years ago a series of unusually dry seasons reduced the level of the lake below that of its outlet; (third), that it remained sufficiently long without circulation to become charged with salts, which have given the water a markedly peculiar and unpleasant taste, unlike that of ordinary fresh water, and also an exceptional power of corroding metal and leather; (fourth), that unusually wet seasons set in some five or six years ago, raising the level of the lake; (fifth), that it rose above its normal level, owing to the formation of a barrier in the bed of the Lukuga by rapid vegetable growth, and the depositing of alluvium by the small streams descending from the slopes on either side; and (sixth), that the lake having once overflowed the barrier, soon removed it entirely, thus regaining its original channel and level."

After a short stay with the hospitable and intelligent missionaries at Mtowa, to the north of the Lukuga outlet, and paying a visit to Ujiji, Mr. Thomson set out to make his way back through terrible Urua, where Cameron suffered so much. Here he had to undergo the worst reception he met with during his whole journey; every possible obstacle was placed in his way, every opportunity was taken to insult him and steal his goods, even the very blanket from beneath him when asleep; and it was only by the greatest self-restraint and tact that fighting was avoided and he and his men escaped with their lives. This they were only too glad to do, just before they reached the goal of the expedition, the river Lukuga. Returning to Mtowa, a passage was obtained in Mr. Hore's boat to the south end of the lake. Here Mr. Thomson picked up his men and set out on the return journey. He had intended to go east through Usanga and by the upper waters of the Rufiji, but as the natives were at war this would have been dangerous. So he went north by the east side of Tanganyika, taking occasion to have a good look at the mysterious Lake Hikwa,

which he re-named Lake Leopold. Mr. Thomson did not succeed in reaching the actual shores of the lake.

"The point where we halted was upwards of 7000 feet above the sea, and from the fact that the River Mkafu, which flows into the lake, is only about 3000 feet, at a distance of sixty miles north, I infer that Lake Hikwa is not far from being on a level with Tanganyika. So steeply do the mountains descend, that from the place where we halted we could almost throw stones into the lake; only we lost sight of them before they reached the ground. The general altitude of the surrounding ranges must be quite 8000 to 9000 feet, and they extend in a quite unbroken line all round. At the north end I calculate the breadth of the lake at about twelve miles. Further south the breadth varies from fifteen to twenty miles. Longitudinally it lies north-north-east and south-south-west. Its length, from native report and from my proximity to it in passing between Nyassa and Tanganyika, I conclude to be certainly not less than sixty miles, probably seventy. Between the mountains and the shores there lies a narrow dark green strip of smooth land, apparently representing a once higher level. On this there are many villages, and the ground is highly cultivated. At the north end, as I have already stated, this strip broadens out into a marshy expanse, formed doubtless by the detritus of the River Mkafu."

Although the waters are almost certainly fresh, yet the lake seems to have no outlet. Without accident or obstacle to speak of, the Expedition, proceeding by Unyamyembe, reached Zanzibar, not much more than a year after it set out from Behobeho. Mr. Thomson, with good reason, congratulates himself that he never needed to fire a shot either in offence or defence, and that, besides the loss of Mr. Johnston, he left only one man behind him.

The Expedition is in many ways one of the most successful that ever entered Africa. Not only was it conducted with unusual efficiency, not only were the chiefs and people, with few exceptions, friendly throughout, but for the first time we have obtained trustworthy observations on the geology of the great lake region of Central Africa. The main conclusions reached by Mr. Thomson have already been described by himself in these pages. But he did not confine himself to geology. He gives us a fair idea of the general character of the country traversed, its mineral, vegetable, and animal productions, the characteristics and habits of the people, the nature of the work being done by missionaries, and the capacities of the country for industrial development. On the last point his views are far from being sanguine. He maintains that the resources of Central Africa have been greatly exaggerated, especially as to its minerals. We are inclined to think that on this point he has taken much too gloomy a view, and that, whatever may be the case with the region actually visited by him, there certainly appears to exist, in the districts traversed by Cameron, Livingstone, and more recently by Major Serpa Pinto, stores of iron and copper that may at a future time be turned to great industrial account. Young as Mr. Thomson is, we commend his remarks on missionary work to those whom it most intimately concerns; and we trust that his severe, but evidently just, criticisms on the conduct of the various Belgian expeditions in Africa will receive the attention they deserve from the management of the International African Association. In the Appendices are given notes on the natural history collections, and Mr. Thomson discusses the geology in detail, suggests that at one period the whole of the lake region of Central Africa must have been covered by the sea, the basin of Tanganyika, however, having been formed subsequently by a great fault or narrow depression of great though unknown depth.

Prefixed to the volumes are portraits of Mr. Johnston and Mr. Thomson, and appended a route map and an interesting geological chart.

OUR BOOK SHELF

Marine Algæ of New England and the Adjacent Coast. By Dr. W. J. Farlow. (Washington, 1881.)

THIS valuable essay on the "Marine Algæ of New England" is a reprint from the United States Fish Commission Report for 1879. It includes a list of all the species of sea-weeds, with the exception of the diatoms, which are known to occur on the coast of the United States, from New Jersey to Eastport, Me. Prof. Farlow gives in a compact and more or less popular form a description of the various orders and species, and he adds a short account of the general structure and classification of sea-weeds, so that all persons frequenting the coast of New England are thus furnished with a handy and compact manual of the subject. The fifteen excellent plates drawn by J. H. Blake and W. G. Farlow deserve a special notice, as they give details of structure which will enable the text to be understood by an intelligent student.

Since the appearance (1852-57) of Harvey's classic work on the North American Algæ, but few species have been added to the Flora. This is not perhaps so surprising as regards the Florideæ or Fucoids, to which Harvey paid so much attention; but as regards the unicellular or simple filamentous forms it is a cause of surprise, for Harvey never paid minute attention to these; and it may in part be accounted for that collections do not seem to have been made along the coast in spring. Prof. Farlow gives a most interesting sketch of the geographical distribution of the species met with. Cape Cod is, as was known to Harvey, the dividing line between a marked northern and southern flora, and subsequent observation shows that on the one hand the flora north of the Cape is more decidedly arctic than he supposed, and that on the other hand that south of the Cape is more decidedly that of warm seas. A good share of the commoner species are also natives of Great Britain, another large share are Scandinavian; but while this is the case the marine flora is also marked by the complete absence of many common British species. No members of the order Dictyotaceæ are to be found; no species of Cutleria or Tilopteris are to be met with. The species of Nitophyllum may be said to be wanting. That commonest of our red sea-weeds, *Plocamium coccineum*, is known as native by only one doubtful case. *Fucus canaliculatus*, *Himanthalia lorea* are quite wanting. The nearly ubiquitous *Codium tomentosum* has not yet been found. *Fucus serratus* is very rare, having only one locality recorded for it in the United States and one in Nova Scotia. *Gelidium corneum*, abundant in almost all parts of the world, is only occasionally found in New England, and then only in the starved form known as *G. crinale*.

Prefixed to the orders and genera will be found carefully-written diagnoses, and an artificial key to the genera is also added. The notes in smaller type which are given under the species often contain most valuable critical information, which will command the attention of all phycologists. To the critical students of our native

species of algæ this little manual of the New England species will prove a most welcome volume. They will find in the chapter on the structure and classification facts that were not known in Harvey's day, and which, here collected for them within a brief space, they would otherwise have to search for in the writings of Thuret, Bornet, Janczweski, Rostefinski, Pringsheim, or Reinke.

The Berries and Heaths of Rannoch. (London: G. Bell and Sons, 1881.)

THE berry-bearing plants here described and delineated are eight, viz. *Vaccinium oxycoccos*, *V. Myrtillus*, *V. uliginosum*, *V. vitis Idæa*, *Arctostaphylos uva-ursi*, *A. alpina*, *Empetrum nigrum*, and *Rubus chamæmorus*, all of which do not, strictly speaking, come within the geographical limitation of the title-page. The heaths are three only in number, viz. the common *Erica cinerea* and *Tetralix*, and *Calluna vulgaris*, to which are added two other nearly allied species not actually found within the district, *Andromeda polifolia* and *Loiseleuria* (*Azalea*) *procumbens*. In the letterpress it is not to be expected that anything new could be added to what is already known about these plants; but in an appendix is given a list of the Gaelic names of the various species supplied by the editor of the *Scottish Naturalist*. The coloured plates are exceedingly good and characteristic; but surely it should have been stated that they are taken from Sowerby's "English Botany." The volume is a pretty one to lie on the drawing-room table. A. W. B.

Lehrbuch der Mineralogie. Von Dr. G. Tschermak. I. Lieferung. (Wien: Alfred Hölder, 1881.)

IT is with great pleasure that we have received this instalment of Prof. Tschermak's work, and also learnt from the publisher's introductory note that the rest of the book may be expected during the course of a year. The work is sketched somewhat on the lines of Naumann's well-known "Elemente der Mineralogie," but follows Miller's Mineralogy in the wider scope given to mineral physics. The present number is introductory, and treats of descriptive crystallography, crystal-structure, general mineral physics, and includes a considerable portion of mineral optics. In the crystallography the Millerian notation and the stereographic projection are employed, and the systems are developed from the principle of symmetry in a clear and simple manner. Prof. Tschermak has adopted the four-plane axial system in the rhombohedral system, which is sometimes designated the Bravais-Miller system. Possibly this may appear to non-mathematical students simpler, and may to a certain extent be more easily mastered, but we feel sure that in its practical application to crystallographic problems it does not possess either the elegance or conciseness of the three-plane axial system selected by Prof. Miller. We feel also that it is most unfair to Prof. Miller's memory to attach his name, even in a double-barrelled way, to a system which he steadily refused to adopt. The theories and facts of twin and mimetic crystals are carefully expounded. These constitute a branch of mineralogy which has become of the utmost importance since the application of the microscope in the investigation of the optic properties of minerals. Other sections, which are especially good, are those on mineral inclusions, on the hardness and etching of crystal faces. These contain a large amount of information which is rarely to be found except by a laborious search through scientific periodicals. The book is divided into sections, each dealing with its separate subject, and at the end of each section is a list of the more important literature of the subject. The work so far is excellent, and if, as we have every reason to expect, it be carried through in an equally satisfactory manner, we shall possess a text-book in keeping with the reputation of its author and worthy of the school to which he belongs. W. J. LEWIS

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Panizzi and the Royal Society

THE "Life of Panizzi" by his friend and colleague, Mr. Louis Fagan,[1] is marked by a tone of indiscriminate adulation which disfigures many specimens of modern biography. The hero is perfect, and they who think otherwise are dismissed with words of contempt, or are admonished to go and meditate on their wicked ways and then return in repentant mood to the community of hero-worshippers.

In the Royal Society's treatment of Panizzi, Mr. Fagan endeavours to justify another example of the wolf and the lamb, although it must be owned that in the pamphlets[2] from which the biographer quotes, the lamb's bleatings are sufficiently energetic to lead to the conclusion that he thought himself a match for the wicked wolf.

Mr. Fagan thinks it important "that Panizzi's stormy connection with the Royal Society should be fairly and impartially" stated; although how this can be done without hearing both sides he forgets to say; and yet he professes to give "the proper elucidation of the facts," "the whole circumstances of the case thoroughly weighed and dwelt upon"; how successfully he opposed "the force with which it was attempted to crush the evidence of his superior talent" (vol. i. p. 119), and although "thwarted and impeded at every step, Panizzi at last succeeded in once again proving that right can contend successfully with might" (vol. i. p. 130).

The reader will gain a very lop-sided idea of this quarrel if he trust to Mr. Fagan's account alone; and as in the reviews of this book no one has attempted to ascertain the truth of the matter (which indeed could not be done without access to the Royal Society's papers), I venture, as a member of the present Library Committee, to state the case from the other side, being naturally anxious to sustain the reputation, so unjustly assailed, of a former committee which contained the honoured names of Baily, Beaufort, Children, Greenough, Lubbock, Murchison, Peacock, Roget, and others.[3]

To make a long story short, it is sufficient to state that about the year 1832 the Royal Society wished to bring out a complete catalogue of the books, &c., in its library. As a preliminary step, a list of the mathematical books was compiled and set up in type as a specimen of the kind of work required. In the words of a Council minute, the sheets were "not designed for publication," they being "in a very rough and unfinished state."

In October, 1832, Dr. Roget meeting Mr. Panizzi at dinner, informed him of the Society's intention, and requested him to look over and revise the sheets in question, together with others that might afterwards be forthcoming. This was agreed to, and the first sheets were forwarded to Panizzi, who found so many errors in them that, as he informed Dr. Roget, "although I would never attempt to correct what had been already done, I was ready to undertake a new compilation."

Accordingly on October 16, 1832, the Library Committee resolved to recommend to the Council that Mr. Panizzi be engaged to make a new catalogue according to the mode to be agreed upon by the Committee, he to be paid 30*l.* for every thousand titles, the whole remuneration, however, not to exceed 500*l.*

[1] "The Life of Sir Anthony Panizzi, K.C.B." By Louis Fagan. Two vols., 8vo, 1880.

[2] "A Letter to H.R.H. the President of the Royal Society, on the New Catalogue of the Library of that Institution now in the Press." Pp. 56 and 3. Signed A. Panizzi, and dated January 28, 1837. The last three pages contain a postscript letter to the President, dated November 4, 1837, and a note in which it is stated that the pamphlet was not put into circulation until the latter date, in order that H.R.H. might have an opportunity of replying to it.

The President, not having availed himself of this opportunity, the second pamphlet was put forth. It is entitled "Observations on the Address by the President, and on the Statement by the Council to the Fellows of the Royal Society respecting Mr. Panizzi, read at the general meeting, November 30, 1837." Pp. 24. Dated December 22, 1837.

[3] Strictly speaking there were three committees, namely, one for the catalogue, a second for the library, and a third for deciding in doubtful cases under what division a book should be placed in the new catalogue.

Panizzi agreed to these terms, and offered "to wait on the Committee, as soon as convenient to them, to settle the manner in which they wish the work to be executed."

Now the whole gist of this quarrel consists in this, that the Library Committee naturally wished to control Mr. Panizzi in his mode of executing the work, while he refused to be controlled or interfered with in any manner. He even regarded as personal enemies all those who attempted so to interfere. He fancied that every one who differed from him was actuated by a sense of personal dislike. When he refused Dr. Roget's request to revise the sheets of the Catalogue, he says (p. 6): "I had no idea when I so candidly expressed my opinion that I was making a powerful and unrelenting enemy in one of the most influential officers of the Royal Society." At p. 51 he says: "so gratuitous an insult would never have been allowed had not Mr. Baily filled the chair at that meeting." And again (p. 5), "My statements will be received with derision by those who know that they may be unjust with impunity." At p. 18 he charges the Committee with "indelicate conduct," at p. 22 with "absurdity," at p. 25 such things were done "purposely to annoy me;" and again, "No suggestion of mine would ever be attended to by the Council." At p. 26 his work was regarded with "a malignant eye;" at p. 28 "The annoyance was incessant," "injurious and unjust;" at p. 33, "treating me as if I were their servant," "unwarrantable liberty;" p. 38, "unjustly interfered with;" p. 41, "insulted with an order of submitting my work to revision. . . . I shall never consent for any one, be he who he may, to make any alterations in it." And when, on June 24, 1836, he was requested to attend the Library Committee on the following Monday at 4 p.m., he declined on the ground that "when I attended before I was not so well satisfied with my position as to wish to be in it again." At p. 54, when clamouring for payment of an unascertained balance which he claimed, he charges the Council with not meaning "to pay it unless they be compelled to it. . . . Possibly there is some legal means of obtaining redress; but in a country like this justice is not a luxury for a poor man to indulge in; and the Council, having at their disposal the funds of the Royal Society, can amuse themselves without personal trouble or loss with a law-suit which I have not the means of sustaining." Will it be believed, in the face of such language as this that Panizzi had already been paid the sum of 450*l.*, and his whole remuneration was not to exceed 500*l.*

In his second pamphlet (p. 18), after charging the Council with not meaning to act fairly, he hurls at it his "unmixed disgust and contempt." But I cannot help thinking that these vigorous epithets would have been more appropriate had they travelled the other way.

When requested to return the printer's revises, and he refused on the ground that they were his own property, together with the key of a drawer in one of the Royal Society's rooms, and he also refused, what wonder that, after so long a contest with this cantankerous man, the Council should have resolved on July 14, 1837, "that Mr. Panizzi be no longer employed in the formation of the Catalogue."

The reader may well exclaim by this time, What *is* all this hubbub about? Simply this: Mr. Panizzi insisted on adding to some of the items of the Catalogue original comments of his own, to which the Library Committee justly objected as committing the Society to opinions of doubtful value. Panizzi attached the greatest importance to these notes and comments. "The Committee, far from objecting to them, ought to have been thankful that I had taken the trouble of introducing them" (p. 31); and he proceeds to quote specimens illustrative of this part of his work. For example, he says: "To the 'Mémoires' of Charnières on the observations of the longitude, I added this note: 'All the author's additions and corrections carefully put in by J. B.' This note is on the title-page of this copy, and the volume is interspersed with alterations in manuscript. I suppose J. B. to mean James Bradley." Later on in the same page he adds: "The author's additions, if put in by Bradley, are, of course, of much more value than if written by any other J. B."

Now the book in question is only a single Mémoire of De Charnières, not a collection of "Mémoires," as described by Panizzi. Moreover, there are five reasons why the additions and corrections could not have been written in by Dr. Bradley.

1. He died five years before the memoir by Dr. Charnières was published. This may well excuse the other four reasons, but they are curious as illustrating the carelessness of a man who was convinced of his own infallibility.

2. The writing of the anonymous J. B. is small and neat: that of Bradley large and awkward. The Royal Society had in its possession manuscripts of Bradley and his signature, which could be seen by merely asking the assistant-secretary for them, and yet Panizzi did not submit the writing of J. B. to this simple test.

3. Bradley was not in the habit of writing in his books.

4. The so-called "additions and corrections" are simply the corrigenda collected into eight pages at the end of the book, and transferred in MSS. to the text, a fidgety piece of work, not likely to be undertaken by so busy a man as Bradley.

5. At the end of the book J. B. drops his incognito and appears as *J. Bevis*, a fact overlooked by Panizzi.

Other similar examples might be given, and indeed were submitted to the Fellows of the Royal Society at the time, in order to justify the resolution of the Library Committee "that all comments or notes expressing matters of opinion on the articles in the catalogue be omitted"; but the statement of them would occupy too much space, dealing as they do with details which unless given in full would not be understood.

Mr. Panizzi was undoubtedly a vigorous clever man; but in the matter of books, he, unfortunately for his own reputation, aspired to universal knowledge which belongs to no one. The gold of a universalist is apt to shrink down into dross when tested in the crucible of a specialist. Having occasion to consult a book by Gay-Lussac, and not finding it in the Catalogue of the British Museum Library, the attendant requested me to write the name and title on a slip and show it to Mr. Panizzi. No sooner had he glanced at the slip than he exclaimed "Ah! you have made a mistake: it is Guy-Lussac!" This readiness on all occasions to say something apparently to the purpose, may impress subordinates with a sense of power on the part of their chief, but to tell a chemist that Gay-Lussac is Guy-Lussac would be much the same as telling him that potash and soda are identical compounds.

C. TOMLINSON

Highgate, N., August 2

The Oldest Fossil Insects

IN a paper on "The Devonian Insects of New Brunswick" (*Bull. Mus. Compar. Zoology*, 1881, vol. viii. No. 14) I have drawn attention to the fact that a fern on the same slab with Platephemera was determined in 1868 by Prof. Geinitz as *Pecopteris plumosa*, and therefore the slab considered by him as belonging to the Carboniferous. I believed that here an important gap was still to be filled, namely, the reliable determination of the fern, which is not mentioned in Mr. S. H. Scudder's monograph, nor in Principal Dawson's note on the geological relation of those insects, which closes Mr. Scudder's paper.

A paper by Mr. Dawson (*Canad. Naturalist*, 1881, vol. x. No. 2) is intended to fill this gap. The fern is after the study of the original specimen determined as *Pecopteris serrulata*, and said to be a common species in those beds. If I am not entirely mistaken it will be difficult to agree with Mr. Dawson's opinion (*l.c.* p. 2) "that doubts and suspicions thus cast on work carefully and exhaustively done should not seriously affect the minds of naturalists," as it happens that in his work of 1880 this common species is not quoted at all among the plants found in those beds, except in a note (p. 41) stating that in the beds 6 to 8 three or four other species occur, among them *probably P. serrulata*. Mr. Dawson quotes for the species the figures 207 to 209 in his Report of 1870, but I confess to be unable to recognise the Platephemera fern in those figures.

Prof. O. Heer has kindly drawn my attention to his "Flora Fossilis Arctica of Bear Island, Spitzbergen, 1871." He has given (pp. 14, 15) a detailed review of the fossil plants from St. John's, New Brunswick, and, as he still believes, has proven that those layers do not belong to the Devonian but to the Ursa stage of the Lower Carboniferous. This important and elaborate statement is disposed of by Mr. Dawson, as far as I know, only in his report, 1873, p. 8, in the following words:—"The so-called Ursa stage of Heer includes this (Lower Carboniferous), but he has united it with Devonian beds, so that the name cannot be used except for the local development of these beds at Bear Island."

It is true that Mr. Dawson, in the supplement to the third edition of the "Acadian Geology," 1878, p. 72, has tried to explain the different opinion of Prof. Heer by the earlier introduction of the Palæozoic flora in American formations. But this fact, known by every one, and of course by Prof. Heer, is not considered by him to be a sufficient objection to the statements given in the "Flora of Bear Island."

The paper of Prof. Heer states carefully and exhaustively the

facts which induced him to consider those layers at St. John's as belonging to the Lower Carboniferous. Therefore naturalists will scarcely agree that such a statement, made by a prominent and acknowledged authority, can be cancelled by a simple negation not supported by facts. Till this is done in a reliable manner, those oldest insects will have to be considered as belonging to the Lower Carboniferous.

Cambridge, Mass., July 25 H. A. HAGEN

The True Coefficient of Mortality

THE very interesting and suggestive lecture of Alexander Buchan on "The Weather and Health of London" (NATURE, vol. xxiv. p. 143 *et seq.*) reminds me of the propriety of calling the attention of writers on "vital statistics" to a point in relation to the true method of discussing the mortuary data. The specific point to which attention is drawn is the necessity of estimating the relative tendency to special diseases by comparing the number of deaths from the given cause with the number of persons living at the ages embraced in the record; instead of making the comparison (as is usually done) with the total deaths from all causes, or with the total number living at all ages.

In like manner, in discussing the influence of age on the mortality from any given disease, it is very common to prepare tables of the number of deaths at each age, and in some instances these numbers have been assumed to represent the relative tendency to the disease at different ages. It is scarcely necessary to say that this is a very serious error, for it must be borne in mind that the number of persons living at different ages is very unequal. Indeed it is self-evident that the true coefficient of mortality for any given disease at any given age is expressed by the ratio of the number of deaths from the specified disease at the given age to the number of persons living at the same age: or, as it may be otherwise indicated, the number of deaths from the given disease at the given age per 1000 persons living at the same age.

In illustrating this point I shall select cancer, because, in relation to the influence of age, it furnishes an extreme case, and thus affords a glaring instance of the fallacy of taking any basis of comparison other than the number of persons living at each age. The mortuary records of the Department of Seine in France, during the eleven years, from 1830 to 1840 inclusive, furnish a total of 9118 deaths from cancer, 2163 males and 6955 females. The following table relating to the mean annual mortality from this disease among females will illustrate this point:—

Age. Years.	Number of females living.	Mean annual deaths from cancer among females.	Annual deaths from cancer in 1000 females living at all ages.	Annual deaths from cancer in 1000 females living at each age.
(1)	(2)	(3)	(4)	(5)
0 to 10	139,840	1·273	—	0·00910
10 ,, 20	115,269	1·182	—	0·01026
20 ,, 30	104,342	15·364	0·04196	0·14725
30 ,, 40	73,203	74·727	0·20409	1·02081
40 ,, 50	54,124	148·727	0·40619	2·74788
50 ,, 60	36,800	147·273	0·40221	4·00198
60 ,, 70	25,703	133·545	0·36472	5·19564
70 ,, 80	12,852	83·364	0·22767	6·48659
80 ,, 90	3680	24·818	0·06778	6·74408
90 ,, 100	340	2·000	0·00546	5·88769
All ages.	566,153	632·273	—	1·11679

The foregoing table demonstrates the inaccuracy of the popular impression that the tendency to cancer attains its maximum between the ages of 35 and 50 years. The numbers in columns (3) and (4) might seem to support such an opinion; but, as we have seen, those in column (5) are evidently the true indices of the tendency to this disease at different ages; and it will be observed that the mortality goes on steadily augmenting with each succeeding decade of age up to 90 years. The fact likely to be most strongly impressed on the reader by the numbers in column (5) is the remarkable regularity of increase of the coefficient of mortality for cancer with advancing life among females after the age of 25 or 30 years. Between the ages of 25 and 75 the mortality increases nearly in arithmetical progression as the age advances in arithmetical progression, the average increment being about 1·30 per 1000 living at each age for each decade. Assuming this to be the law of mortality from cancer among females, it admits of very simple mathematical expression. Thus, let

A = the age at which liability to cancer begins.

A′ = any age greater than A.

C = constant coefficient, variable according to country, state of civilisation, &c.

Then we have—Annual mortality per 1000 living at age A′ = C (A′ − A).

In our table representing the mortality from cancer in the department of the Seine from 1830 to 1840 inclusive, the value of A may be taken = 25, and C = 0·13; hence we have—Annual mortality per 1000 living at age A′ = 0·13 (A′ − 25). Thus by the formula the mortality at 55 = 3·90, and column (5) gives 4·00 between 50 and 60; at 75, formula = 6·50; table = 6·49 between 70 and 80.

The mortality from cancer seems to be vastly smaller in England than it is in France, so that a less value must be given to the constant C. The foregoing formula represents the law of increasing mortality with advancing life in the simplest form, as a function of the age. This extreme simplicity is probably unique in the case of cancer, and seems to indicate that age is so far the controlling element in the development of this disease as to overpower all other causes. In the case of other diseases we cannot expect to escape the necessity of employing those exponential functions in investigating their laws of mortality, which are essential when a multiplicity of causes are in operation.

Many years ago the attention of the medical profession in this country was called to the fact that the available mortuary data were not discussed in a manner which revealed the true value of the facts contained in the numbers.[1] But there is reason to believe that Prof. Francis A. Walker, the intelligent superintendent of the census of the United States for 1880, will not overlook this point when he comes to the discussion of the mortuary statistics which have been collected.

Berkeley, California, July 7 JOHN LE CONTE

[Mr. Le Conte does not appear to have apprehended the point discussed in the lecture on "The Weather and Health of London"—that point in no part of the inquiry being the tendency to the disease at different ages, but the manner of the distribution of deaths in the case of each disease through the weeks of the year, with the view of arriving at some knowledge of the influence of season in determining that distribution. Only in one case, viz., in discussing the rates of the mortality from diarrhœa in several large towns, was a reference to population required, and in that case the curves were drawn, showing the weekly rate of mortality per 1000 of the population of the respective towns.—ALEXANDER BUCHAN.]

Bisected Humble Bees

I TOO have frequently observed humble bees lying dead or stupefied under lime-trees, sun-flowers, and some other plants, and once I saw a Staphylinus, commonly known as Black Cock-tail, or Devil's Coach-horse, nip a humble bee in two, and on passing that way later I found that it had cleared out the honey-bag and left the two halves of the bee on the path, as described by your correspondent. I have known boys catch humble bees and eat the honey in them; and probably many other animals have learned how to get at the sweet drop.

Trinity College, Cambridge THOS. McK. HUGHES

AT your request for information on the above I beg to say that I have observed both the flycatchers alluded to by your correspondent, and also the little blue tit (*Parus cærulea*) attack the humble bees in the manner described, to extract the honey-bag. This attacking the bees is not, so far as my experience goes, a general characteristic of these birds, and what should lead them to it occasionally I cannot ascertain.

Exeter, August 15 EDWARD PARFITT

[1] *Vide* papers by the writer, entitled "Statistical Researches on Cancer," *Southern Med. and Surg. Journ.*, new series, vol. ii. pp. 257-293, May 1846. Also "Vital Statistics," illustrated by the "Laws of Mortality from Cancer," *Western Lancet*, vol. i. pp. 176-190, March, 1872 (San Francisco).

I NOTICE the same phenomenon here, under the sycamore trees, when they are in blossom, which your correspondent Mr. Masheder observed recently under his lime trees, namely, the heads and thoracic segments of severed humble bees lying on the ground, with legs and wings attached, still retaining their vitality in some cases, but without any trace of the abdominal segments, for the sake of whose contents, no doubt, the bees were destroyed. We have no fly-catchers here. I suspect the tomtits, which are abundant in the vicinity of this wholesale apicide, but I have no direct evidence of their guilt. R. V. D.

Beragh, Co. Tyrone, August 15

Migration of the Wagtail

Apropos of recent letters on this subject in NATURE, permit me to note that on my voyage out to the East Indies in the month of October, 1878, on board the Dutch mail steamer *Celebes*, two wagtails alighted on the ship when not very far north of the equator (the ship's course being then from Aden to Padang in Sumatra). On observing them I pointed them out to a Dutch friend, who at once recognised them as *Kwikstails*. They were rather lively, and did not appear to us to be fatigued; after staying with us for some days they took their departure, but in what direction I had not the satisfaction of observing.

Without affirming positively, I believe the species was the *Motacilla alba*. HENRY FORBES

Sumatra, June

ITALIAN DEEP-SEA EXPLORATION IN THE MEDITERRANEAN

AFTER some delay, beyond our control, the war-steamer of the Italian Royal Navy *Washington*, Capt. G. B. Magnanghi, R.N., left Maddalena on the 2nd inst. on her thallassographic mission. Under the able direction of Capt. Magnaghi, two days were devoted to preliminary dredgings and trawlings in depths from 200 to 1000 metres, principally for testing our apparatus, which works admirably. On the 4th inst. (yesterday afternoon) we did our first deep-sea dredging in 3000 metres; the dredge came up empty, but I had the pleasure of securing, attached to the hempen tangles, a magnificent specimen of that strange blind Crustacean discovered by the *Challenger* in the North Atlantic, and named *Willemœsia leptodactyla;* it is no doubt one of the most characteristic forms of the deep-sea fauna, and its discovery in the Mediterranean is of very great importance and interest, as all students of thalassography will be fully aware, after what Dr. Carpenter has written on the biological conditions of the deeper parts of that sea. Our specimen of *Willemœsia* is slightly smaller than the one dredged by the *Challenger*, and figured in Sir Wyville Thomson's "Atlantic," vol. i. p. 189; but otherwise it differs only in one or two minor details, which may be sexual differences; it was dredged off the west coast of Sardinia.

On account of a slight mishap with our engine we have anchored at Asinara for a couple of days, but shall at once resume our work. HENRY H. GIGLIOLI

Asinara, Sardinia, August 5

KÖNIG'S WAVE-SIREN

EVERY musician is painfully familiar with the fact that two notes nearly, but not quite exactly, in unison with one another, produce, when sounded together, a throbbing sound commonly described as the phenomenon of "*beats*." In the elementary theory of acoustics the cause of beats is shown to be the mutual *interference* of the two vibrations, one sound interfering with the other and silencing it, when one set of waves is half a vibration behind the other. Just as at certain points on the earth's surface there are no tides when a high tide and a low tide coming from different seas meet, so there is no sound when two sets of sound-waves meet in opposite phases. If the two notes differ just a little in pitch they will alternately reinforce and interfere with one another, and produce the throbbing sound of beats, the number of beats (or maxima of sound) per second being the same as the difference in the number of vibrations per second. If one tone makes m vibrations per second and the other n (a slightly smaller number, being a slightly flatter tone) there will be $m - n$ beats per second heard. If this number be not more than 3 or 4 per second the beats can easily be counted. When they get as rapid as 12 or 14 per second they come too fast to be counted, and are very harsh and grating. They are most disagreeable at about 33 per second; and if yet more rapid, are heard as a harsh, disagreeable, rattling sound quite different from a true note. Imperfect octaves and imperfect twelfths likewise cause beats; in fact there are beats heard for any imperfectly tuned consonance in which the frequency of the higher note is 1, 2, 3, 4, 5, . . . or any integer number of times that of the lower.

But along with the disagreeable and throbbing phenomenon of beats there arises another phenomenon when two notes not in unison with one another are simultaneously sounded. This is a low booming tone, to which musicians give the name of the "grave harmonic." If two stopped organ-pipes are brought to unison, and then one of them is sharpened by gradually pushing in its stopper, the beats are heard first slow, then fast, then unendurably rapid. But when they reach about twenty or thirty per second the low booming note begins, and rises gradually in pitch as the beats become too rapid to be discriminated. When the higher note has reached a point about half-way between unison and the octave note, the beats are practically imperceptible, and from this point the phenomena recur again, but in *inverted order*, the grave harmonic falls in pitch down to a low booming tone, while the beats begin again to be distinguishable, grow harsher, then become slower, until when the interval of the octave is reached they also disappear.

A great controversy with respect to these low tones of the grave harmonics has arisen in recent years, and though it smoulders from month to month, occasionally blazes up into vigorous flame. The controverted question is, What are these grave harmonics, and to what are they due? Also, What becomes of the *beats* when they occur so rapidly that the ear cannot distinguish them? The answer given by Dr. Thomas Young, and by Smith in his "Harmonics" (1749), was that the rapid beats actually passed into the grave harmonic, just as in the generation of any pure tone the separate vibrations (which, when very slow, are heard as separate sounds) blend into one continuous tone whose pitch depends upon their frequency. This view is maintained at the present day with great energy also by the famous acoustician Dr. Rudolph König of Paris. On the other hand, Helmholtz has emphatically maintained that the grave harmonic is not, and cannot be, thus accounted for, and has given very cogent reasons for thinking that it has another explanation; and in this view he is supported by Preyer, Lord Rayleigh, Ellis, Bosanquet, and all the best English physicists. Mere alternations of sound and silence, however rapidly they occur, cannot produce the same effect on the mechanism of the ear as a pure to-and-fro motion of the same periodic frequency. A tuning-fork which vibrates 100 times per second will give out waves which, falling on the ear, push the drumskin in, and draw it back that number of times per second. But a continuous tone interrupted 100 times per second by short periods of silence produces quite a different mechanical action on the mechanism of the ear. The writer of this article once tried to ascertain, by the experiment of rotating a vibrating tuning-fork upon its axis, whether the alternations of sound and silence which are observed as it is rotated would blend into a continuous tone; but no kind of blending took place. Another most conclusive proof that the beats and the beat-tones are distinct phenomena is that at a

certain speed both can be heard going on simultaneously. Helmholtz gives to the grave harmonic the name of "*difference-tone*," because its number of vibrations exactly corresponds to the difference between the number of vibrations of the primaries. Two notes whose frequencies are respectively m per second and n per second will give rise to a difference-tone whose frequence is $m-n$ per second, which is, in fact, just the same number as the number of beats between the two. König uses a different name, and agreeably to his (and Young's) theory, calls these notes "*beat-notes*," and classifies them into two sets, *lower* and *upper*, the lower beat-note being that corresponding to the beats between the lower note and the one that is sharper than it, the higher beat-note being that corresponding to the beats between the higher note and the octave of the lower. For example, if the notes c' and d'' are sounded together, their frequencies being in the ratio 8 : 9, there will be heard a beat-note whose frequency is relatively 1, or three octaves below the lower note. If c' and b' (a seventh) are sounded, their frequencies being in the ratio 8 : 15, there will be heard a beat-note of the upper series of relative frequency 1 (being the difference between 15 and 16), or also three octaves below the c'. So also the interval between c' and $\sharp f''$ (the twelfth-tone flattened by about a semitone, so as to make the ratio 8 : 23) will also give a beat-tone of relative frequency 1, being the difference between 23 and 24.

Now on Helmholtz's theory beats can only arise between vibrations so near together on the scale as to act on the same fibre of Corti in the ear (provided the vibrations be pure and free from upper partial tones), and they should therefore be audible not as *two tones* but as fluctuations in loudness of *one* tone. But when c' and d' are sounded we certainly hear *two separate* tones *plus* the low note which we call the grave harmonic. Helmholtz has therefore concluded that another explanation must be sought, and this he finds in a mathematical investigation of the resultant displacements due to super-

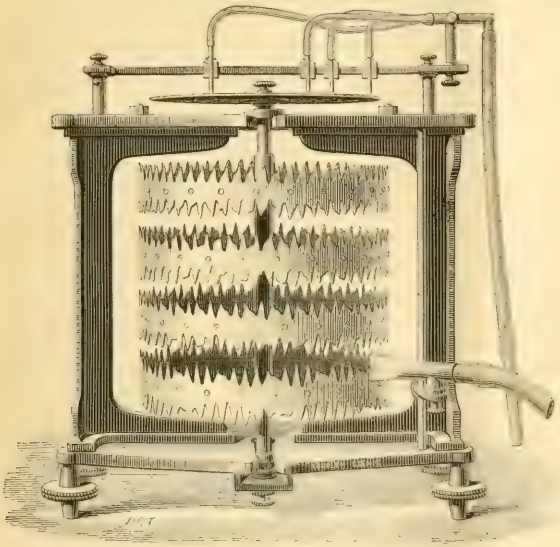

FIG. 1.

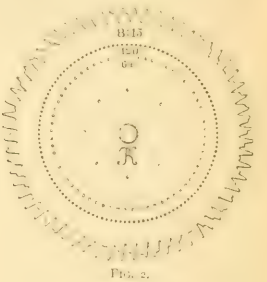

FIG. 2.

FIG. 3.

posing two tones, on the supposition that the vibrations of the primaries are so large that the moving forces are no longer simply proportional to the displacement, but are influenced by the squares or higher powers of them. He has shown that when this is the case combinational tones *must* arise whose frequencies correspond to the difference in the number of vibrations, and he further conjectures that to the dissymmetry of the drumskin and other vibrating parts of the ear is due the fact that the *squares* of the displacements can thus affect the resultant vibration. If so, all the combinational tones other than those of mistuned unisons must really arise in the ear itself and be *subjective* in character, as indeed Mr. Bosanquet, who has lately studied the matter most carefully, roundly declares.

Dr. König, however, undaunted by Helmholtz's reasonings, has returned to the contest with new weapons. He has repeated all his former experiments with new tuning-forks specially made of massive form, so as to be yet more perfect in tone, and finds his observations on beat-tones confirmed. He has further constructed a new instrument, the *wave-siren*, with which to establish his doctrine that *beats*, when too rapid to be heard separately, blend into a *beat-note*. In this instrument vibrations are set up in the air by blowing through a slit against the edges of a notched disk or rim which rotates rapidly upon an axis. In 1872 Dr. König constructed sirens on this principle, the indentations at the edges of the disks being simple harmonic curves, or "wave-forms," which therefore gave rise to simple tones. In the new wave-siren (Fig. 1) the indentations are determined in the following manner :—Two simple vibrations whose ratio is known are mechanically compounded together by machinery, and a resultant curve is obtained which *exactly* corresponds on a large scale to the resultant motion of the air when the two notes having this interval are sounded together. This compound curve is then set off very exactly round the periphery of a metal disk, and cut out in the metal with the utmost nicety. Fig. 2 shows the form of the curve (set out on the edge of a *flat* disk) for the interval of

the seventh, the ratio being 8 : 15. When this disk is rotated rapidly, and wind is blown through a flat nozzle held with its opening radially at the edge, two notes are heard giving this exact interval. *If the vibration is slow, beats are heard: if the vibration be rapid, the beat-note is heard.* In order to compare these notes the more accurately with a true combinational tone, the same disk is pierced by three concentric rings of holes, one with 64, another with 120, giving the ratio 8 : 15, and another, with 8 holes only, corresponding to the number of beats between 120 and the octave of the 64 set (128), that is to say, to the upper beat-note of the interval 8 : 15. When air is blown through the rings of 64 and 120 holes in the rotating siren-disk, exactly the same notes and same beats or beat-notes are produced as by the wave-curve at the edge. Here there can surely be no partial tones present to complicate the phenomenon. For greater convenience in comparing several combinations, the wave-forms are cut upon cylindrical rims mounted upon one axis as in the first figure, a flat disk pierced with holes being added above for comparison. In every case slow rotation gives beats, and rapid rotation the beat-note exactly as König's theory requires.

It remains yet to be seen what answer Helmholtz and the mathematical acousticians will give to the challenge thrown down by König in this beautiful and ingenious piece of mechanism. Meantime we may mention that Mr. Bosanquet of Oxford has just been examining the very same question, though by different means. He finds that all König's higher beat-tones can be accounted for by the assumption that the terms of higher orders become important in the mechanism of the ear when the displacements are considerable, and that therefore "by transformation" in this sense the variations of maximum displacement in the resultant wave give rise to to-and-fro vibrations of simple form having the same frequency as these variations, and therefore evoke *in the ear* a note whose frequency is the same as the number of beats. He is also positive that such tones exist only in the ear, and are inaudible in resonators. Lastly, he has satisfied himself that in all the cases of beats between mistuned consonances in which the higher note is (nearly) 2, 3, 4, . . . &c., times as rapid as the lower, *the beat consists of variations of intensity of the* lower *of the two primary tones.*

S. P. T.

HYDRODYNAMIC ANALOGIES TO ELECTRICITY AND MAGNETISM

FROM a scientific and purely theoretical point of view there is no object in the whole of the Electrical Exhibition at Paris of greater interest than the remarkable collection of apparatus exhibited by Dr. C. A. Bjerknes of Christiania, and intended to show the fundamental phenomena of electricity and magnetism by the analogous ones of hydrodynamics. I will try to give a clear account of these experiments and the apparatus employed; but no description can convey any idea of the wonderful beauty of the actual experiments, whilst the mechanism itself is also of most exquisite construction. Every result which is thus shown by experiment had been previously predicted by Prof. Bjerknes as the result of his mathematical investigations.

It has long been known that if a tuning-fork be struck and held near to a light object like a balloon it attracts it. This is an old experiment, and the theory of it has been worked out more than once. Among others Sir William Thomson gave the theory in the *Philosophical Magazine* in 1867. In general words the explanation is that the air in the neighbourhood of the tuning-fork is rarefied by the agitation which it experiences. Consequently the pressure of the air is greater as the distance from the tuning-fork increases. Thus the pressure on the far side of the balloon is greater than that on the near side, and the balloon is attracted.

Dr. Bjerknes has followed out the theory of this action until he has succeeded in illustrating most of the fundamental phenomena of electricity and magnetism. He causes vibrations to take place in a trough of water about six inches deep. He uses a pair of cylinders fitted with pistons which are moved in and out by a gearing which regulates the length of stroke and also gives great rapidity. These cylinders simply act alternately as air-compressers and expanders, and they can be arranged so that both compress and both expand the air simultaneously, or in such a way that the one expands while the other compresses the air, and *vice versâ*. These cylinders are connected by thin india-rubber tubing and fine metal pipes to the various instruments. A very simple experiment consists in communicating pulsations to a pair of tambours, and observing their mutual actions. They consist each of a ring of metal faced at both sides with india-rubber and connected by a tube with the air-cylinders. One of them is held in the hand; the other is mounted in the water in a manner which leaves it free to move. It is then found that if the pulsations are of the same kind, *i.e.* if both expand and both contract simultaneously, there is attraction. But if one expands while the other contracts, and *vice versâ*, there is repulsion. In fact the phenomenon is the opposite of magnetical and electrical phenomena, for here like poles attract, and unlike poles repel.

Instead of having the pulsation of a drum we may use the oscillation of a sphere; and Dr. Bjerknes has mounted a beautiful piece of apparatus by which the compressions and expansions of air are used to cause a sphere to oscillate in the water. But in this case it must be noticed that opposite sides of the sphere are in opposite phases. In fact the sphere might be expected to act like a magnet; and so it does. If two oscillating spheres be brought near each other, then, if they are both moving to and from each other at the same time, there is attraction; but if one of them be turned round, so that both spheres move in the same direction in their oscillations, then there is repulsion. If one of these spheres be mounted so as to be free to move about a vertical axis, it is found that when a second oscillating sphere is brought near to it, the one which is free turns round its axis and sets itself so that both spheres in their oscillations are approaching each other or receding simultaneously. Two oscillating spheres, mounted at the extremities of an arm, with freedom to move, behave with respect to another oscillating sphere exactly like a magnet in the neighbourhood of another magnetic pole. I believe that these directive effects are perfectly new, both theoretically and experimentally. The professor mounts his rod with a sphere at each end in two ways: (1) so that the oscillations are along the arm, and (2) so that they are perpendicular. In all cases they behave as if each sphere was a little magnet with its axis lying along the direction of oscillation.

Dr. Bjerknes looks upon the water in his trough as being the analogue of Faraday's medium; and he looks upon these attractions and repulsions as being due, not to the action of one body on the other, but to the mutual action of one body and the water in contact with it. Viewed in this light, his first experiment is equivalent to saying that if a vibrating or oscillating body have its motions in the same direction as the water, the body moves away from the centre of disturbance, but if in the opposite direction, towards it. This idea gives us the analogy of dia- and para-magnetism. If, in the neighbourhood of a vibrating drum, we have a cork ball, retained under the water by a thread, the oscillations of the cork are greater than those of the water in contact with it, owing to its small mass, and are consequently *relatively* in the same direction. Accordingly we have repulsion,

corresponding to diamagnetism. If, on the other hand, we hang in the water a ball which is heavier than water, its oscillations are not so great as that of the water in its vicinity, owing to its mass, and consequently the oscillations of the ball relatively to the water are in the opposite direction to those of the water itself, and there is attraction, corresponding to paramagnetism. A rod of cork and another of metal are suspended horizontally by threads in the trough. A vibrating drum is brought near to them; the cork rod sets itself equatorially, and the metal rod axially.

If a pellet of iron be floated by a cork on water and two similar poles (*e.g.* both north) be brought to its vicinity, one above and the other below the pellet, the latter cannot remain exactly in the centre, but will be repelled to a certain distance, beyond which however there is the usual attraction. The reason is that when the pellet is nearly in the line joining the two poles the north pole of the pellet (according to our supposition) is further from this line than the south one. The angle of action is less; so that although the north pole is further away, the horizontal component of the north pole repulsion may be greater than that of the south pole attraction. Dr. Bjerknes reproduces this experiment by causing two drums to pulsate in concord, the one above the other. A pellet fixed to a wire, which is attached by threads to two pieces of cork, is brought between the drums, and it is found impossible to cause it to remain in the centre.

Dr. Bjerknes conceived further the beautiful idea of tracing out the conditions of the vibrations of the water when acted on by pulsating drums. For this purpose he mounted a sphere or cylinder on a thin spring and fixed a fine paint-brush to the top of it. This is put into the water. The vibrations are in most cases so small that they could not be detected, but by regulating the pulsations so as to be isochronous with the vibrations of the spring, a powerful vibration can be set up. When this is done a glass plate mounted on four springs is lowered so as to touch the paint-brush, and the direction of a hydrodynamic line of force is depicted. Thus the whole field is explored and different diagrams are obtained according to the nature of the pulsations. Using two drums pulsating concordantly, we get a figure exactly like that produced by iron filings in a field of two similar magnetic poles. If the pulsations are discordant it is like the figure with two dissimilar poles. Three pulsating drums give a figure identical with that produced by three magnetic poles. The professor had previously calculated that the effects ought to be identical, and I think the same might have been gathered from the formulæ in Sir William Thomson's "Mathematical Theory of Magnetism," but this only enhances the beauty of the experimental confirmation.

Physicists have been in the habit of looking upon magnetism as some kind of molecular rotation. According to the present view it is a rectilinear motion. Physicists have been accustomed to look upon the conception of an isolated magnetic pole as an impossibility, but here, while the oscillating sphere represents a magnetic molecule with north and south poles, the pulsating drum represents an isolated pole. These are new conceptions to the physicist, let us see whither they lead us. The professor shows that if a rectilinear oscillation constitutes magnetism, a circular oscillation must signify an electric current, the axis of oscillation being the direction of the current. According to this view what would be the action of a ring through which a current is passing? If the ring were horizontal the inner parts of the ring would all rise together and all fall together, they would vibrate and produce the same effect as the rectilinear vibrations of a magnet. This is the analogue of the Amperian currents.

To illustrate the condition of the magnetic field in the neighbourhood of electric currents, Dr. Bjerknes mounted two wooden cylinders on vertical axes, connecting them by link-work, which enabled him to vibrate them in the same or opposite ways. To produce enough friction he was forced to employ syrup in place of water. The figures which are produced on the glass plate are in every case the same as those which are produced by iron filings in the neighbourhood of electric currents, including the case of currents going in parallel and in opposite directions.

The theory is carried out a step further to explain the attraction and subsequent repulsion after contact of an electrified and a neutral substance and the passage of a spark. But it is extremely speculative, and is not as yet experimentally illustrated, and I think that at present it is better to pass it by.

I believe that the professor will exhibit his experiments and give some account of his mathematical investigations, which have occupied his time for five years, to the Académie des Sciences this afternoon. His results have not been published before. GEORGE FORBES

Paris, August 15

NOTES

JOHN DUNCAN, the Alford weaver-botanist, has at last passed away, and his dust now lies under the earth whose beautiful children he knew and loved so well. He expired a little after noon on the 9th instant, in his eighty-seventh year, and was buried on the 16th in the old churchyard at Alford, in a selected spot, where a monument will soon be raised to his memory by the free-will offerings of those who admired his high character and pure-minded enthusiasm for science. The poor old man has not lived long to enjoy the comforts lately provided for him, but it is pleasant to think that this aged and unselfish student of nature passed the last days of his long and silent life in comparative affluence, and that he now rests in no pauper's grave. His life was so recently sketched in these pages (NATURE, vol. xxiii. p. 269) that it is unnecessary here again to rehearse it. In December last, when it was ascertained that, after an unusually laborious life, winning his daily bread by weaving, carried on till beyond his eighty-fifth year, he had through failing strength been at last reluctantly forced to fall on the parish for bare support, an appeal was made in his favour by Mr. Jolly, H.M. Inspector of Schools, in the newspaper press throughout the country, and in our own columns. The response was speedy and ample, so that in a very short time a sum of 326*l.* was spontaneously sent for his relief, with every expression of admiration and regret from all parts of the land, and from most of our most eminent scientific men, whose kindly appreciation of his scientific labours was not unfrequently very aptly and memorably put. His pride and appreciation of all this kindness were genuine, deep, and child-like, and were expressed not seldom in piquant and touching terms; so that his numerous friends have the great satisfaction of thinking, that by their means, though he has departed sooner than was anticipated, they have helped to comfort the evening of his days. His constitution was of the healthiest type, and his tenacity of life remarkable in a frame so exhausted, and he only passed away when the last particle of the expiring taper was slowly consumed. As already told in NATURE (vol. xxiv. p. 6), the money raised in John Duncan's behoof has been vested in seven trustees, under a trust-deed executed during his life. By its provisions his valuable books on botany and other sciences are bequeathed to the parish library of Alford for the use of the district; and all remaining funds are to be safely invested and the interest to be devoted for all time to the foundation of certain prizes, to be called by his name, for the promotion of the study of natural science, especially botany, amongst the children in certain parishes in and round the Vale of Alford. A memoir of the old man is now being written by Mr. Jolly, and will be anticipated with interest.

In the death, on the 27th ult., of Mr. Hewett Cottrell Watson, at the age of seventy-seven, English botany has lost one of her most indefatigable workers. For the space of fifty years Mr. Watson has been a prolific writer on the geographical distribution of British plants, and on the distinguishing characters of the more "critical" species; and in these departments of botany he has left very few who can approach him in the extent and the accuracy of his knowledge. In addition to many smaller publications, and a vast number of contributions to periodical literature, the principal works with which his name will be associated are the "New Botanists' Guide" (1835–7), the "Cybele Britannica" (1847–59), and the numerous editions of the "London Catalogue of British Plants." His garden at Thames Ditton had long been an object of pilgrimage to botanists desirous of seeing growing specimens of rare or little-known species or varieties of British plants; and his judgment was the last appeal in questions of difficulty. In 1847 he spent three months investigating the flora of the Azores, which was then very little known, and added about 100 species to the flora of the Archipelago, many of which were new to science. Throughout life Mr. Watson was an ardent believer in phrenology; when a student at the University of Edinburgh he became acquainted with George and Andrew Combe; and was for a time editor of the *Phrenological Journal*.

Prof. Raoul Pictet of Geneva, who has been giving his attention of late to marine architecture, announces, according to the *Times* correspondent, a discovery which, if his anticipations be realised, will effect a revolution in the art of shipbuilding and greatly augment the speed of sea-going and other ships. The discovery consists in a new method of construction and such an arrangement of the keel as will diminish the resistance of the water to the lowest possible point. Vessels built in the fashion devised by Prof. Pictet, instead of sinking their prows in the water as their speed increases, will rise out of the water the faster they go, in such a way that the only parts exposed to the friction of the water will be the sides of the hull and the neighbourhood of the wheel. In other words, ships thus constructed, instead of pushing their way through the water, will glide over it. According to the professor's calculations, in the accuracy of which he has the fullest confidence, steamers built after his design will attain a speed of from 50 to 60 kilometres the hour. A model steamer on the principle he has discovered is in course of construction at Geneva. The machinery has been ordered at Winterthur, and when ready the new vessel will make her trial trip on Lake Leman.

The Electrical Exhibition, though now open to the public, seems far from being completely arranged. Our Paris correspondent writes that the English section was opened on Sunday, a result due to the personal exertions of the Earl of Crawford, the English Commissioner, which has caused great satisfaction. The organisation of the English section is highly approved. The evening sittings have been postponed for an indefinite number of days, owing to a series of mistakes in the engineering department. The electrical railway is not ready. In spite of these drawbacks the receipts of the first three days were from 4000 to 5000 francs each. On Sunday they were largely increased, although the fees were diminished by half. We hope shortly to refer to the Exhibition in detail. Independently of the Catalogue, the administration of the Exhibition has published a handbook on Electricity and its Applications, by Armingaud, Becquerel, Bert, Blanco, Breguet, Clerac, Deprez, Fontaine, Mascart, Reynaud, and others. *L'Électricité* has published a "Petit Vocabulaire raisonné" of every word used by electricians, with an introduction by W. de Fonvielle.

It is announced that Miss Pogson, daughter of the Madras Government Astronomer, has been appointed Meteorological Reporter to the Government of that Presidency. Miss Pogson has for some years discharged with great ability the duties of Assistant Government Astronomer.

We believe that the Royal Commission which has been constituted for the purpose of inquiring into and reporting upon the facilities for technical education in various countries is now practically complete. It will comprise Messrs. Samuelson, Slagg, Stevenson, and Woodall, the members respectively for Banbury, Manchester, South Shields, and Stoke-upon-Trent. Mr. Swire Smith of Huddersfield, Prof. Roscoe of Manchester, and Mr. Philip Magnus, the director of the City and Guilds of London Institute, have also accepted invitations, and Mr. G. R. Redgrave of the Science and Art Department will probably be selected to accompany the Commission as secretary. It is expected that the Commission will commence its travels about the middle of October.

The British Association having decided to hold its annual meeting for 1882 at Southampton, a large and influential committee, including the Corporation and magistrates of the borough and the clergy and ministers of all denominations, has been appointed to make the necessary arrangements. A subscription and guarantee fund to cover the requisite expenses of the meeting has been commenced.

The meeting of the International Congress at Bordeaux on the Phylloxera having been antedated to August 29, is now postponed, on account of the elections, till October 10.

The Epping Forest and County of Essex Naturalists' Field Club held a Field Meeting at Chelmsford on Saturday, August 13, in conjunction with the subscribers to the "Essex and Chelmsford Museum." The Chelmsford Museum was visited under the guidance of the Rev. R. E. Bartlett, M.A., the hon. curator, and Mr. E. Durrant, the hon. secretary. After lunch the whole party proceeded in drags to Danbury Hill, the ancient camp of which was visited under the guidance of Mr. H. Corder; the company then assembled to hear an address by Prof. G. S. Boulger on "The Origin and Distribution of the British Flora." About six o'clock the party returned to Chelmsford to tea at the "Saracen's Head" Hotel, and an ordinary meeting of the Essex Club was held, the President, Mr. R. Meldola, occupying the chair. The President communicated on behalf of General Pitt-Rivers the report on the excavation of the ancient earthwork at Ambresbury Banks in Epping Forest. It appears that this investigation has been carried out with considerable success, a number of fragments of pottery of British construction having been found beneath the rampart on or near the old surface of the ground. The Club has thus so far settled the date of the camp by a single cutting, and the current theory that it was the work of the Romans must be abandoned. Although undoubtedly British, further excavations will be required before it can be decided whether it dates from before or after the Roman conquest. We are glad to see that the Great Eastern Railway Company has assisted the Club to a great extent by allowing the members to travel at greatly reduced fares on any of their lines within the County of Essex on the occasion of field or of ordinary meetings.

The *Daily News* correspondent writes that the Swiss Seismological Commission, which, by the co-operation of its numerous members and correspondents, continues the work of simultaneous earthquake observation, has just issued a report on the earthquake of July 22. This shock was felt over a wide area. In France it extended over the departments of Drôme, Isère, Savoy, Upper Savoy, Saône et Loire, Ain, Jura, and Doubs. In Italy it affected chiefly the high valleys of North-Western Piedmont. In Switzerland the movement was observed in the cantons of Geneva, Vaud, Friburg, Neuchâtel, Solothurn, Basel, and the

western districts of Aargau and Berne. From Valence to Basel, and from Chalons-sur-Saône to Suza and Zinzal, the region of disturbance included both sides of the Jura Mountains, besides traversing the great chain of the Alps. It affected an area 350 kilometres long and 250 kilometres wide, equal to 8000 square kilometres of surface. There were two very slight shocks on the evening of July 21, and a feeble shock at 12.10 on the morning of the 22nd. The principal shock, which took place at 2.48 a.m., was followed at 3.30 and 4.30 by two oscillations that were only just perceptible to the senses. The great shock consisted of two quakes and several smaller, but distinct, vibrations. In some localities as many as ten vibrations were counted. Relatively to its extent, the shock was intense; in the neighbourhood of Chambéry and Aix-les-Bains, chimneys fell and walls were fissured. In Switzerland the shock was stronger near the Jura than nearer the Alps, and especially strong at Geneva, in Vaud, and in Neuchâtel. Prof. Forel, who edits the report, remarks on the singular variations in the intensity and direction of the shock even in the same neighbourhood. These differences, which have been observed in previous earthquakes, are too great to be due solely to errors of observation. An earthquake is often more felt in one quarter of a town than in another; and as this variation is irregular, a locality that hardly feels a shock at all on one occasion feeling it on another, it cannot arise from differences in the density of the underlying strata. Prof. Forel offers no explanation of this phenomenon, albeit he thinks it ought to be explained, and craves for it the particular attention of his brother seismologists.

DR. K. VON FRITSCH of Halle discusses the subject of earthquakes in the last issue of the *Verhandlungen* of the Berlin Geographical Society. He maintains that the cause of earthquakes must be sought for at a rather small depth, the greatest depth ascertained not exceeding ten to fourteen miles, and usually far less, whilst rather feeble forces produce earthquakes which are felt at great distances. It is known that Krupp's hammer, which weighs 1000 centners. and falls from a height of three metres, produces sensible concussions on a surface of eight kilometres diameter; whilst the recent explosion of the Leimbach dynamite manufactory was felt at Halle and Merseburg, forty-one and forty-five kilometres distant. Whilst showing how easily concussions are produced by causes comparatively feeble, Dr. Fritsch points out how earthquakes might be and must be produced by the increase and decrease of volume of rocks under the influence of physical and chemical forces, and by concussions, by the opening of crevices in rocks, and by the subsidence of masses of rocks due to these agencies. Many schists are subjected, as is known, to extension, and when crevices arise the schists must enter into oscillations which must produce very varied phenomena, according to the direction and the force of the oscillations, much like to what we see in the oscillations of tuning-plates. Dr. Fritsch concludes by saying that future researches as to the causes of earthquakes ought to be directed especially to the study of the geotectonical conditions of the localities where they occur.

IN the course of the excavations for the new fort at Lier, in the neighbourhood of Antwerp, a number of bones of extinct animals, mammoth's teeth, and the almost complete skeleton of a rhinoceros have been dug up. It was in the same district that, in 1760, was found the immense skeleton of a mammoth, which has been preserved in the Natural History Museum at Brussels.

THE Faure accumulators have been tried again by the Paris Omnibus Company on a tramway with a carriage arranged for the purpose. The experiment is said to have been highly successful.

THE Committee formed some time ago for the exploration of the subsidences in Blackheath have published a report, in which, while giving an account of their proceedings, and the opinions of various geologists for the probable causes of the subsidences, they themselves have come to no definite conclusion.

A CONGRESS has been opened at Bordeaux on the education of the deaf and dumb. In connection therewith the *Journal Officiel* publishes a series of articles by M. Claveau, General Inspector of "Établissements de Bienfaisance," who tries to prove that the method of teaching the deaf and dumb how to speak was invented and practised by St. John of Beverley, Archbishop of York, in 865, and fully described by the Venerable Bede.

THE Meteorological "Centralanstalt" founded by the Swiss Naturalists' Society at Zurich has become a Government Institution by a decree of the Swiss Senate, and now bears the title "Swiss Meteorological Centralanstalt." Herr R. Billwiller has been appointed director, while the Swiss Home Secretary and a special Commission will superintend the Institution.

THE Royal University Bill (Ireland) on Tuesday night last was read a third time in the House of Commons, having been sent down from the House of Lords. It now only awaits the Royal Assent. The programme of the Natural Science course seems framed in accordance with modern views, and when the Scholarships and Exhibitions shall be finally settled by the Senate, we will probably refer again to the subject.

WE notice in the last number of the *Zeitschrift* of the Berlin Geographical Society (vol. xvi. fascicule 3) an interesting description of spring in Madagascar, from the pen of the late Herr J. M. Hildebrandt, who died on May 29 at Antananarivo. Spring arrives about the middle of November, when the cold south-eastern wind which blew throughout the winter, leaving its moisture on the eastern slopes of the highlands, covered with thick forests, and driving before it the savannah fires, gives place to the north-western wind which brings warmth and moisture. The revival of nature under the influence of this wind is well described by Herr Hildebrandt, and his paper contains valuable information as to the flora and fauna of Madagascar.

THE additions to the Zoological Society's Gardens during the past week include an Orange-winged Amazon (*Chrysotis amazonica*) from South America, presented by Mr. R. Seyd; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Sir Patrick Colquhoun; a Herring Gull (*Larus argentatus*), British, presented by Mr. E. A. Brown; a White-crested Touracou (*Corythaix albocristata*) from South Africa, presented by Capt. T. G. Steer; a Black-eared Marmoset (*Hapale penicillata*) from South-East Brazil, presented by Mrs. Alsop; an American Tapir, ♂ (*Tapirus terrestris*) from Trinidad, presented by Herr Fritz Zurcher; two West Indian Agutis (*Dasyprocta cristata*), three Garden's Night Herons (*Nycticorax gardeni*), and two Martinican Doves (*Zenaida martinicana*) from the Antilles, presented by Mr. H. T. Burford Hancock, F.Z.S.; two Stock Doves (*Columba œnas*), British, presented by Mr. A. E. C. Streatfield; two Topela Finches (*Munia topela*) from China, a Nutmeg Finch (*Munia punctularia*) from India, a Javan Nutmeg Finch (*Munia nisoria*) from Java, a Francis Eagle Owl (*Bubo pœcnsis*) from West Africa, two Aldrovandi's Skinks (*Plestiodon auratus*), and two Pantherine Toads (*Bufo pantherinus*) from North Africa, a Bay Antelope (*Cephalophus dorsalis*) and a Water Chevrotain (*Hyomoschus aquaticus*) from West Africa, purchased; and two Common Marmosets (*Hapale jacchus*) from Brazil, deposited. In the Insectarium may be seen full-fed larvæ, now spinning up, of the Atlas (*Attacus atlas*) and Ailanthus (*Attacus cynthia*) Silk-Moths, also freshly-hatched ones of the Marbled White Butterfly (*Arge galatea*) and Scarlet Tiger Moth (*Callimorpha dominula*). Amongst the aquatic forms

examples of *Hydrous piceus* (the large Water-Beetle), *Pelobius hermanni*, *Notonecta glauca* and *Argyroneta aquatica* are at present exhibited.

GEOGRAPHICAL NOTES

THE current number of the Geographical Society's *Proceedings* gives the paper recently read by Mr. Whymper on some of the geographical results of his expedition among the the Ecuadorian Andes, with a diagram of his routes, while Mr. W. G. Lock supplies a contribution on Iceland, which is published at a convenient season for tourists. Mr. Lock's paper refers chiefly to the Askja volcano, the largest in the island, and is illustrated by a map of the east coast of Iceland. In the "Geographical Notes" a brief reference is made to this season's Arctic expeditions, and we are informed that Mr. Leigh Smith has lately sailed from Peterhead on his fifth Arctic expedition; and on reaching Franz-Josef Land he intends to construct a house and refuge at Eira Harbour, and afterwards to get as far north as possible. A very interesting account is given, from a letter recently sent home by M. de Brazza, of the results of his explorations and of the advantages of his route to Stanley Pool by the Ogowé as compared with Mr. Stanley's along the north bank of the Congo. After some news respecting Russian travellers an account is given of Messrs. Soltau's and Stevenson's journey from the Irawaddy to the Yangtsze, to which we recently referred. Under "Correspondence" is a letter from Major H. G. Raverty on the Dara'h of Nur, which does not leave a pleasant impression on the reader's mind.

LORD ABERDARE has finally accepted the office of representative of the British Government at the International Congress of Geographers at Venice, and he will of course act as chief delegate of the Geographical Society. The India Office and the Admiralty are sending maps, charts, &c., to the Exhibition, and the former will be represented by Lieut.-General Sir H. Thuillier, late Surveyor-General of India, and the latter by Sir F. J. Evans, Hydrographer of the Navy. It is probable that nothing further will be done to represent this country officially, as the Treasury sternly decline to furnish funds.

THE Italian North-African explorers, Massari and Matteucci, to whose journey we have repeatedly referred, instead of returning by Tripoli, as was expected, struck across the Continent and came out at the Gulf of Guinea. Only a few days ago they arrived at Liverpool, and it is sad to record that, after so successfully accomplishing an arduous work, Dr. Matteucci has succumbed to African fever. He died on the morning of his arrival in London last week; his body has been conveyed to his native city, Bologna. Matteucci was only twenty-nine years of age.

LETTERS from Zanzibar of the 1st ult. notify the arrival there of Mr. Thomson, the African traveller, whose services have been engaged by the Sultan to examine and report on the mineralogy of the mainland. It is his Highness's wish that Mr. Thomson's first surveys should be devoted to the discovery of coal mines, of which several are said to exist not far from the coast. His Highness writes that he intends sending the explorer shortly to Makindarry, which is to be the centre of his future operations.

LETTERS from the steamer *Oscar Dickson* have been received at Gothenburg. The steamer, as our readers will remember, was frozen in at the mouth of the Yenisei River in 72° lat. N., and between 76° and 77° long. E. The winter was successfully passed, the difficulties the crew experienced were great, however. The sun was below the horizon for seventy days, and the cold rose to − 41° C. During March and April enormous masses of snow fell, so that it covered the ice to a height of seven feet above the ship's deck; the thickness of the ice was seven and a half feet.

WHAT might have been the climate during the Glacial Period is the subject of an interesting paper published by Dr. Woeikoff in the last issue of the *Zeitschrift* of the Berlin Geographical Society (vol. xvi. fasc. 3). It is well established now that for the formation of glaciers, not only a sufficiently low temperature is necessary, but also a sufficient supply of moisture in the atmosphere. Thus, on the Woznesensky gold-mine, which lies at a height of 920 metres and has a mean temperature of − 9° Celsius, but a rather dry climate, we have no glaciers, nor in the Verkhoyansk Mountains, where the mean temperature is as low as − 15°·6, and the temperature of January is − 48°·6. To show these differences Dr. Woeikoff perpares a table of the temperatures at the lowest ends of glaciers, and we see from his figures that, whilst in Western Norway, at the end of the Jostedal glacier (400 metres high), the mean temperature is 4°·8 Cels., 5°·8 at the end of the Mont Blanc glaciers (1099 metres), 6°·8 at the Karakorum glaciers in Tibet (3012 metres), and even 7° on the western slope (212 metres) of the New Zealand highlands, and 10° on the eastern slope (835 metres). In other countries, as, for instance, on the Mounkou Sardyk Mountain, in Eastern Siberia (3270 metres), the mean temperature at the end of the glaciers is as low as − 10°·2, and − 2°·4 in the Daghestan Mountains of the Caucasus. Thus the difference of mean temperatures at the lower ends of glaciers reaches as much as fully 20°. Besides we see that, provided the quantity of rain and snow is great, glaciers descend as low as 212 metres above the sea-level in a country (New Zealand) which has the latitude of Nice and the mean temperature of Vienna and Brussels, that is, higher than that of Geneva, Odessa, and Astrakhan, whilst the average temperature of winter is higher there than that at Florence. Further, Dr. Woeikoff discusses the rather neglected influence of large masses of snow upon the temperature of a country during the summer, and by means of very interesting calculations he shows how much the temperature of summer in higher latitudes is below what it ought to be in consequence of heat received from the sun, and *vice versâ* during the winter, these differences being due on the one side to the refrigerating power of snow, and on the other side to the heating power of sea-currents. In a following paper he proposes to discuss the other causes which might have influenced the climate of different parts of the earth during the Glacial period.

WE notice in the *Verhandlungen* of the Berlin Geographical Society (vol. viii. fascicule 5) a full report on the surveys which were made in the Russian Empire, including Caucasus, Siberia, Turkestan, and the Orenburg military district, during the year 1880. This is translated from the official report published in the organ of the Ministry of War.

DURING the last session of the German Reichstag, Dr. Thilenius, Prof. Virchow, and Herr von Wedell Malchow presented a petition to the Government requesting the participation of Germany in the exploration of the Polar regions proposed by the late Karl Weyprecht in the interest of meteorology, geology, and other sciences. It is now announced that the German Government will probably soon take steps in this direction, and will first give its principal attention to securing the co-operation of other nations.

HEFT VIII. of Petermann's *Mittheilungen* begins with a paper by Dr. Danckelman on the Temperature Conditions of the Russian Empire, after Dr. Wild. The other papers are on M. Desiré Charnay's Expedition in Central America, Dr. I. B. Balfour's visit to Socotra, the Irawaddy above Bamo according to the data collected by the Indian Pundit in 1879–80 (with a map), and an article on the unfortunate Flatters Expedition by Dr. Rohlfs.

IN the *Bulletin* of the Antwerp Geographical Society (tome vi. 2e fasc.) is a paper of much interest by Dr. Delgeur on the Geographical Knowledge of the Ancient Egyptians.

MESSRS. LONGMANS AND STANFORD have published an enlarged edition of the Alpine Club Map of Switzerland. As it is issued in a number of separate sheets, it ought to prove useful to tourists.

THE Geographical Society of Lisbon has resolved to send an exploring party into the Sierra d'Estrella for scientific investigation. The mountain chain in question has never been scientifically explored.

IN 1879 Mr. L. Loth, a Government surveyor in Dutch Guiana, made a survey of a considerable portion of the River Saramaca, and his map of its course, on the scale of 1 : 400,000, together with an account of his expedition, has lately been published in the *Transactions* of the Amsterdam Geographical Society.

THE *Oesterreichische Monatsschrift für den Orient* of this month contains an interesting article on the new Conseil de Santé et d'Hygiène publique en Egypte by Prof. v. Sigmund, a well-known authority of the Medical High College of Vienna. Amongst various other papers we may mention an essay on Japanese paper manufacture by Dr. Rudel of Dresden, and an article on the wines of Cyprus by Dr. Richter of Larnaca.

SOLAR PHYSICS—THE CHEMISTRY OF THE SUN[1]

The Test supplied by Change of Refrangibility

WE have then got so far. Limiting our studies to iron we find that the prominence spectrum is made up of one set of lines seen in the terrestrial spectrum, and the spot spectrum made up of another set. And more than this, if we add the lines seen in the prominence and spot spectra together we do not then by any means make up the complete spectrum.

It is fair to ask the following question :—Have we any other means of establishing this extraordinary fact of the separation of the iron lines in spots and storms? We have. Reference has already been made to the change of refrangibility of the lines brought about by the change of velocity of movement of the various solar vapours. But if, as already hinted, the lines of iron behave to each other in precisely the same way as the lines of two perfectly distinct substances behave to each other; then if we observe changes of refrangibility in the iron lines, both in spots and flames, we should get the same differentiation as we have already got in the lines thickened or intensified in the spectra of spots and flames.

We will now see the results which have been obtained along this line of research, and it should be pointed out that it is not a method by which it is easy in a short time to accumulate a large number of observations, because metallic prominences are very rare except at the sun-spot maximum, and in the case of spots we not only want a spot, but we want that spot to be in a very considerable state of commotion, in order that the change of refrangibility may be obvious enough to enable us to record the phenomena.

So far as this inquiry has gone at present we have only observed the lines contorted in spots.

In the diagram (Fig. 37) the zig-zag lines indicate the iron lines which changed their refrangibility in a number of spots observed at the end of last year. The point is that, although we have a great many of the iron lines bent, twisted, contorted—with their refrangibility changed, yet some of the iron lines mixed with them give us no indication of movement. All these observations have been made upon lines seen at the same moment in the same field of view. Observations of this nature exist twelve years old, but no importance can be attached to them, for the reason that the phenomenon was not understood, as I hope it is understood now, and precautions were not taken in the observations then made to show that no motion of the slit across the spot took place in the interval between the two observations. For, of course, it is not fair to compare a line which one sees in one part of the spectrum with a line seen in another, unless one is absolutely certain that the slit has not moved on the sun's image; because one-thousandth part of an inch on the sun's image means a good many miles on the sun. Referring to Fig. 37 we have, at wave-length 5366–70, three lines, two in motion, and one at rest, all belonging to a well-known group of iron lines. At a later date we have the line at 5382 at rest, while that at 5378 is in motion. Thus it will be seen that these points and others prove there is just as much individuality in the way in which the lines of iron change their refrangibility as there is in the way in which one particular line, and then another, is thickened in a sun-spot or brightened in a prominence; and if we go further we find this very interesting and additional fact, that the lines which are not contorted are in a great many cases precisely those lines which are seen in the flames, but not in the spots.

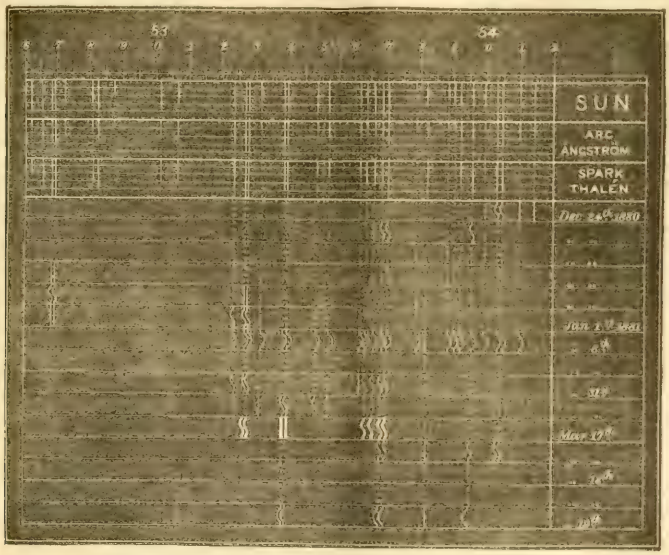

FIG. 37.—Different rates of motion registered by different iron lines.

It is seen therefore that the evidence afforded by change of refrangibility is of like nature to that afforded by the thickening of lines in spots and brightening of lines in flames.

The explanation which lies on the surface is that the vapours in the flames produce one set of lines in one place or at a certain temperature, and the vapours in the spots produce another.

Sometimes these vapours are mixed up by up-or-down rushes, and sometimes therefore the lines are common.

Bearing of these Observations on the Origin of the Fraunhofer Lines

At the end of the last lecture it was pointed out that the observations we are now discussing seem to indicate that in time we may be able to say that the absorption to which any particular Fraunhofer line is due takes place in a certain region of the solar atmosphere, whereas formerly we could only say that it was produced by absorption *somewhere*.

[1] Lectures in the Course on Solar Physics at South Kensington (see p. 150). Revised from shorthand notes. Continued from p. 324.

The time has now come, I think, to go into this question in more detail.

Let us consider the maps. Of the 96 iron lines in that first region which we considered only 4 are seen in the flames; 92 of those therefore must not be looked for in the flame region, for the reason that twelve years of patient work have not divulged their existence. Again of these same 96 lines only about 32 are seen in the spots at all extensively affected. It is useless therefore to look for the remaining 60 lines or thereabouts in the same spot region, for the reason that they have been looked for for a long time without being seen equally widened.

Of course it must be remembered that these changes are due to *change of intensity*, and that other lines may be there of an intensity so low that they have escaped the keen eyes of those anxious to chronicle them. Still it will be acknowledged, I think, that the method of treatment I have adopted is the best open to us, and is a fair one on the whole.

The facts being so, it looks really as if the origin of the mass of the absorption to which the Fraunhofer spectrum of iron is due is to be sought in a region of the solar atmosphere much nearer to the place assigned to it by Kirchhoff originally than to that lower region where we considered we were driven to place it when the new method was first established. When the new method had been working for some considerable time observers recorded hydrogen with magnesium underlying it, and with sodium underlying that. And since they were metals of low atomic weight and vapour density we were justified in considering them as occupying the highest levels—the very extreme limit of the solar atmosphere.

It was therefore fair to argue that if the substances of the lowest atomic weights were really close to the photosphere, those of highest atomic weights were really in the photosphere itself, and therefore, being in the photosphere, the absorption by means of which we were able to determine their existence really took place in or near the photosphere.

This later work, I think, seems to show that that view requires reconsideration; and it may well be that subsequent work will show that those Fraunhofer lines, which we do not trace in flames and which we do not trace in the spots, are probably absorbed in a cooler, higher region of the atmosphere, much more nearly occupying the place assigned to the general atmosphere by Kirchhoff than that which has been given to it by later observers. If we accept this the work becomes a little plainer, and the reason that we get such an excessively simple spectrum in the lower reaches of the sun is because the more complex vapours exist at a considerable elevation above them, and as the interior of the sun must be hotter than any of its envelopes, no cold substances—nothing approaching the solid state which we have learnt for many years gives us the most complete spectrum of the substance—nothing approaching a solid can enter those charmed regions.

Therefore we are also again driven to the view that these cooler vapours—vapours much nearer the solid state, much more condensed, much more complex than those which can exist alone in the hottest layer—probably originate the great mass of absorption; that is, many lines not traced either in spots or flames are produced in the higher regions.

If this be so, the Fraunhofer spectrum is really not the spectrum of any particular part of the sun; but because it contains lines thickened in the spots, lines brightened in the flames, and other lines about which we know nothing, it must really be the summation of the absorption of the different strata which compose the solar atmosphere; so that chemically the solar atmosphere, with regard to the iron spectrum, gets more and more complex every mile we go upwards. Of course, too, if this is good for iron it is good for every other substance which we believe to exist in, or to have some connection with, the solar atmosphere.

Further Test supplied by this View

If this be so we really can go on with our tests; we can bring the laboratory into the field, and we must learn in our laboratory experiments to make abstraction of those lines which are due to the more complex masses reduced by the transcendental temperature which we employ, if there is any truth in the view that I am bringing before you. In a laboratory experiment, for instance, when we want to observe the vapour of iron we have to employ two poles of solid iron. We have no means, such as are afforded us by the sun, of shielding the precise part we want to observe by a considerable number of envelopes of gradually-increasing temperature, so that even if we can get the highest temperature in the laboratory this result of the highest temperature will be cloaked, masked, and hidden by all those results, by all those simplifications which have been brought about to produce that precise effect of the highest temperature. So that the only thing we can do is to watch the intensities of the lines when we considerably change our temperature. I am speaking now of iron. I will show by and by that for some other substances there is a method which enables us to get over this excessive difficulty, for no doubt a very great difficulty it is; but in the case of iron, that really is the only thing that remains to us. Fig. 38 will give an idea of the way in which we may be misled if we do not examine our light source with the greatest care. It is engraved from a photograph of the spectrum taken between two poles of a Siemens machine, moistened with a salt of calcium, an image of the vertical poles having been thrown on the vertical slit.

It is seen how wonderfully we get the simplifications brought about by the electric current, depicting themselves in two perfectly distinct ways. The lower part gives the spectrum of the positive pole, and the upper part of the spectrum of the negative pole. In the first place it will be seen that there is no axis of symmetry for these lines; some of them elongate considerably in one direction; others of them elongate considerably in the other; some of them are exceedingly short, and only appear close to that region of the negative pole where the lines broaden; others again are brighter in the region much nearer the middle of the field. Others of the lines start from a region far removed from the arc; others again seem to start almost in the arc itself. Now this not only reminds one of what one sees in a solar storm, but it shows us most distinctly that even in the electric arc, when

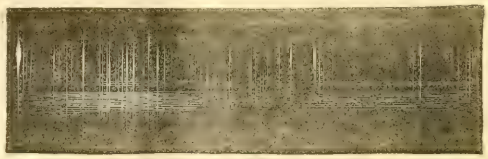

FIG. 38.—Photograph of the spectrum of the poles, showing that the lines start and end in different levels.

we have had time to study it sufficiently, these very simplifications which we have been so long in search of may be recognised eventually and permanently recorded.

Tests supplied by the Variations between Solar and Terrestrial Spectra

Attention has been called to Kirchhoff's statement that the existence of the terrestrial elements in the sun is established by the fact of the coincidence of wave-length and *intensity* between the lines visible in our laboratories and the lines recorded as existing in the solar spectrum.

We have now arrived at a point when we can discuss this with advantage.

I propose to show first that the statement is not true; and, secondly, how the tests supplied by the variations from terrestrial spectra can be explained on, and bring most valuable confirmation to, my view. We are now able to say that at least two causes are at work, and they will require to be discussed separately.

But first as to the facts. We have already seen what enormous differences there are in the spectrum of calcium under different conditions. In the diagram of the calcium spectrum (Fig. 28) we saw that H and K, the most important lines in

the sun, are really thin lines at the temperature of the electric arc, but that they kept intensifying and were rendered visible almost alone, when, instead of using the electric arc we used an induced current of considerable tension. But when we pass from the case of calcium, which occupied the attention of solar observers several years ago, to other elements, and when we go still more into the minute anatomy of the thing, we find that the further we go the less final is the statement that the matching in intensity of the lines is perfect.

Nor is this all. *Not only is the matching less perfect in intensity, but whole reaches of lines in various spectra are left out which cannot be accounted for on the long and short principle.* It has been before pointed out that of the 26 lines of aluminium, 2 only being left in the solar spectrum is easily explained, because the 24 dropped were short lines. But when we come to other elements, we find of adjacent lines—lines of equal length, and which, so far as we can gather, ought to be equally represented in the sun—one is absent, and one is present, probably with more intensity than it would seem to deserve from its behaviour among other lines of the spectrum. A table will best exhibit the sort of variation that crops up and insists on being recorded when the solar spectrum is photographed in anything like the detail which it absolutely demands. The method of recording will be at once understood.

Metal.	Wave-length.	Intensity in sun. 1=darkest.	Intensity in photograph. 1=brightest.	Intensity. Thalèn. 1=brightest.	
Mn	4083·0	4	2	5	
	4083·5	3	2	3	
Fe	4197·5	1	2	–	
	4198·1	3	2	–	Stronger line.
Co	4118·0	2	1	–	
	4120·5	4	1	–	Stronger line.
Ni	4458·6	2	2	–	
	4647·8	3	2	5	
Cr	4344·4	4	3	2	
	4351·8	3	3	2	
Mo	4706·5	3	1	4	
	4757·5	0	1	4	
W	4842·0	5	1	1	
	4887·5	3	2	2	
Ti	3980·8	2	1	–	
	3989·25	1	1	–	
Zn	4679·5	3	1	1	
	4721·4	4	1	1	
Pt	4442·0	4	2	4	
	4551·8	3	2	2	
Pd	3893·0	1	1	–	
	3958·0	3	1	–	Stronger line.
Zr	3957·22	2	1	–	
	3990·45	3	1	–	Stronger line.
Di	3989·65	0	1	–	
	3993·98	3	1	–	
Rb	4201·0	0	1	2	Stronger line.
	4215·5	3	1	0	

Now if Kirchhoff's view be anything like a representation of the whole truth there ought not to be any difference between these intensities; the line least intense in the photograph ought to be least intense in Thalèn's tables, and if it existed in the sun at all, it ought to be least intense amongst the Fraunhoferic lines, but as a matter of fact, there is an absolute inversion. The cobalt line 4120·5 is four times as intense in the sun as in the photograph; in the titanium line 3989·25 the intensities are equal; while in tungsten 4842·0 they are inverted, being represented as of minimum intensity in the sun, and maximum by Thalèn and in the photograph. In the sun one of the lines of iron is given as of first, and the other as of third intensity, while in the photograph they are both of second order. Again, in didymium we get a first order line recorded in the photograph which is absent from the sun altogether, whereas another line of the first order near it is there as a line of small intensity; so also in rubidium, and so we might go on. Indeed it is evident that the moment we go into minute details in this work we find that the general statement requires a very considerable amount of modification. And in addition to that too, there comes the question, how on this theory of the identity of the nature of the substances in the earth and the sun, are we to account for the bright lines seen in the sun itself—for the bright lines seen in the photosphere, to say nothing of those seen in the chromosphere—which have no corresponding Fraunhofer lines at all—lines so numerous that in a prominence of moderate complexity we may say that half the lines are absolutely unknown to us? Now when the other lines observable under these conditions—lines which we can get accurately, are lines known to us (we are dealing with the product of the very highest temperatures which we can command) we are justified, I think, in imagining that these lines which we do not get at, are lines which we could get at if we could proceed a little further. They elude our grasp; we know nothing about them; we put a query against them all because we cannot get at that stage of temperature at which they are produced.

There is one very beautiful case of this kind that comes out from Tacchini's observations (Fig. 39). From the beginning of February, 1872, Tacchini had observed the two iron lines 4922·5, 5016·5, when suddenly the whole rhythm of his observation was broken, and at the end of December, 1872, these iron lines ceased to be visible in the flames altogether.

On no one occasion after this for some time was either of these iron lines observable, but from January to September, 1873, he saw two lines of wave-lengths, 4943 and 5031, about which absolutely nothing whatever is known; so that it really is, I think, a perfectly justifiable suggestion that these lines are the spectrum of a substance which exists in the flames which is produced at a much higher temperature than that needed to give us those other forms of "iron" which produce the lines in the spots.

That is a suggestion which is obvious from a reference to the maps, and if it is correct we must acknowledge that when the sun was in that intense state of quiescence that there were no downward currents—nothing to bring the cooler vapours from the higher regions of the sun down to obstruct the general tenour of the solar way in the flame region, that at last, in consequence of this wonderful tranquillity, even the iron lines—the only two lines which indicate the presence of iron in the flames—faded away because iron, as we know it, faded away. There is no other explanation that I know of. In addition to those two lines we have two other lines about which we know nothing, except that they are probably due to a temperature which we cannot approach.

Special Test with regard to Iron

Part of the work which has been undertaken in connection with this special branch of the investigation, has been a careful inquiry into the changes brought about in the spectrum of iron by exposing it to as widely different temperatures as possible. The research is a very laborious one, and it may be some day we shall get a very much better record than that which my assistants and myself have produced; what we have been able to do we have done over the region of the spectrum which we have already worked over in the spots and flames.

In different horizons we have recorded the results observed when we use either the arc or the coil, or the oxyhydrogen flame or the Bessemer flame or some other light-source, and we vary in each case, as far as can be, the temperature employed. For instance, when we use the quantity coil we use a big jar, a little jar, and no jar at all; and the same with the intensity coil. Now if this map is carefully studied,[1] it will be seen that the intensity of the lines is very considerably changed when we pass from one set of observations taken under one set of conditions, to another set taken under other conditions. It is not a mere question of dropping out the lines when we pass from the temperature of the arc to the temperature of the coil, but it really is a considerable intensification of certain of the lines under certain conditions. There are three conditions under which we get the two lines 5339 and 5340, and they are not seen afterwards. The line 5433 is seen rather faint in the sun and very strong in the Bessemer flame. 5197·5 is very faint in the sun, but its intensity is doubled and even trebled with certain conditions of the quantity coil. I have introduced these facts to point a remark about Kirchhoff's statement; when Kirchhoff made that statement he was amply justified by the science of the time. He was familiar naturally with the spectrum of iron, which he had studied in his own laboratory, and other good observations of the spectrum of iron had been recorded in his time. But, with observations like these before one, which

[1] The map is too large and too detailed to be reproduced here.

one must take into account; it is too *coarse* a statement—I do not use the word in any offensive sense—to say that the iron lines in the sun correspond with the iron lines seen on the earth. Which iron lines—which of these horizons—are to be taken? It will be seen in a moment, if there are differences between these horizons, that if we take any one, we throw all the others out of court, and we have no right to do that; so that statement about the coincidence in the intensity could not be made with the facts now at our disposal. Any one wishing to make that statement would have to go over that work, and he would, following it honestly, I believe, find that the statement was true in no instance whatever. Fig. 40, which is an engraving from a photograph, will show the kind of difference one gets, even when one deals with the electric arc, which undoubtedly gives an iron spectrum which is the nearest approximation to the Fraunhoferic spectrum. The lines at wave-lengths 4325·0, 4300·7, 4271·0 are three of the strongest iron lines in the arc spectrum, and those at 4071·0, 4063·0, 4045·0 are also strong iron lines, though less strong than the others. Now it will be seen that in the solar spectrum the last three are much more important, much thicker, and much darker than the first, so that here is an absolute inversion in the thickness of the lines. I

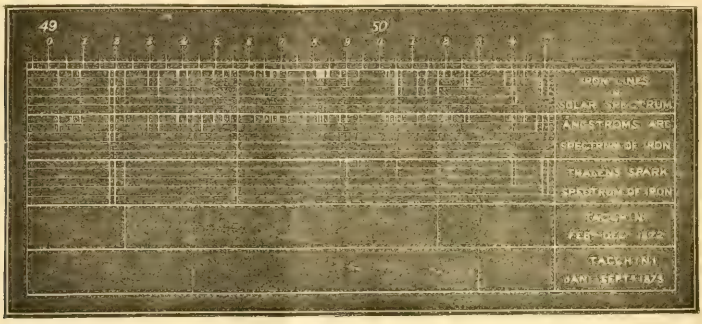

FIG. 39.

appeal to the photograph because there is no partiality about it; it has no view, no anxiety therefore to intensify one particular part of it at the expense of the other. This photograph is referred to only as the exemplar of many similar reversals which we see whenever such observations are made.

Let us now take some iron lines which have been studied in spots and storms, and consider the differences in their intensity among the Fraunhofer lines. We may also note the changes brought about in our laboratories.

The diagram (Fig. 41) gives the main results in a convenient manner. It does not profess to go over the whole ground, but I think it will enable me to point out the way in which the phenomena observed on the sun are re-echoed and endorsed by the work which has been done in the laboratory,

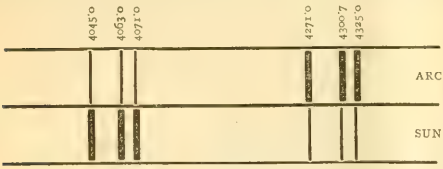

FIG. 40.—Anomalous reversals (iron) from a photograph.

and how severe the tests applied have been, and how well the view has borne the strain.

The diagram refers to three lines visible in the first map—three lines that in an instrument of ordinary dispersion might easily be mistaken for a single line in the sun. We have, as before, the intensities among the Fraunhofer lines recorded in the upper part of the diagram; we then go to our photographs of the arc, and find that the line at 4923·2 is entirely absent. We then pass on to the quantity coil, which gives us the three lines; but there is a difference between the intensities of the lines as seen in the quantity coil with a jar, and the lines seen in the sun, 4918 being thinner than in the sun. If we take the jar out of circuit 4923·2 almost disappears, and we get very nearly the same result as we get from the arc. We then try the intensity coil, which is supposed to give us an equivalent or higher temperature than the quantity coil does. What do we find there? That 4923·2 is enormously expanded and developed, apparently at the expense of 4918, which becomes thin. Taking the jar out, we come back to a result which is very much like the solar spectrum, with the difference, however, that 4918 is somewhat less intense than in the sun. Then come the facts which have already been brought forward throughout with special reference to these particular lines, that the two lines which are seen alone in the arc are seen alone in the spots, or at all events in 73 spots out of 100; and the other line which is so enormously

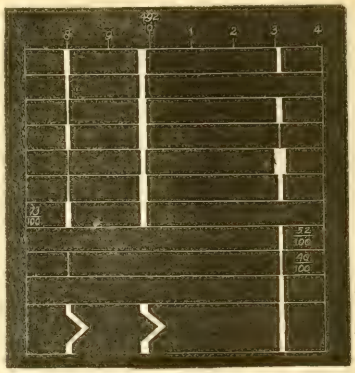

FIG. 41.—[illegible] showing the behaviour of three iron lines under different conditions, solar and terrestrial. 1, solar spectrum; 2, arc; 3, quantity coil with jar; 4, quantity coil without jar; 5, intensity coil with jar; 6, intensity coil without jar; 7, spots observed at Kensington; 8, Prominences observed by Tacchini; 9, prominences observed by Young; 10, reversed in penumbra of spot observed on August 5, 1872, by Young; 11, motion indicated by change of refrangibility.

expanded when we use the highest temperature is seen alone in 52 out of 100 prominences by Tacchini. Again, further connecting this diagram with the last one, we have found in several cases when a change of refrangibility has been observed in the iron lines in the spots visible on the sun that the two lines 4918 and

4919·8 have been affected, while 4923·2 has remained at rest. That will give an idea of the way in which we really do find the laboratory work and the observatory work, each coming to the rescue of the other, each helping us to understand something which, without the other record, would be excessively difficult.

Tests supplied by the Absence of Lines from the Solar Spectrum

It is my conviction that many lines of the different chemical substances are absent from the solar spectrum when that absence cannot be attributed to anything depending upon reduction in the quantity of the substance present. In connection with this point there is an experiment to which attention may now be directed, because it is an attempt to imitate solar conditions somewhat; so that the inquiry is rendered possible as to whether these lines may not owe their absence from the Fraunhofer lines to their being the product of a very low temperature, a temperature which we cannot expect to find in the sun in any regions where the pressure would be sufficient to enable any absorption phenomena to take place. The point of the experiment is this: There are bodies which we can render incandescent at low temperatures. For iron, as we have already seen, we have to use a coil, but such substances as magnesium, sodium, lithium and the like can be volatilised at the temperature of the Bunsen flame, and at that temperature we get a certain spectrum from them. Now a great many different spectra have been recorded by different observers for these bodies, and the question was, could we get any independent method of determining which lines were really due to high and which to low temperatures. Now it is generally conceded that the temperature of the Bunsen flame is lower than the temperature of an induction spark; and we have an arrangement by which we can pass a spark between horizontal platinum poles through a flame in which the substance to be experimented on is volatilised. In this way we can see what change in the spectrum is introduced by the passage from the temperature of the flame to the temperature of the spark. We can fill the flame with the vapour, say of sodium, and observe its spectrum; then when the flame is nicely charged in the region between the two poles, we can pass a spark through it, and by throwing the image of the spark upon the slit of the spectroscope we can first of all get a spectrum of the flame, and then the spectrum also of that particular part of the flame through which the spark is passing. Now we really have got a good deal of light from that method of observation. In the case of magnesium, for instance, the change is very striking (see Fig. 42).

The flame gives us a spectrum in which are seen two lines corresponding with the two least refrangible members (b_1 and b_2) of a very prominent group of lines in the green part of the solar spectrum, and associated with these is a less refrangible line unrepresented in the sun, the whole forming a wide triplet. On passing the spark this last line is very greatly enfeebled, if not abolished altogether, for the very obvious reason that the molecule which gives rise to it is dissociated more rapidly at the temperature of the spark than it is at the temperature of the flame, and as that line dies out another solar line (b_4) appears, the three forming a triplet similar to, but narrower than, that

FIG. 42.—Flame and spark spectra of magnesium.

produced in the flame alone. Kirchhoff showed that potassium was not present in the sun, the line upon which he worked being the red line which is seen when potassium is thrown into a flame. The fact that we get that red line in the flame shows that it is a line produced by a low temperature; the molecule which produces the vibration therefore may probably be one which is produced at a low temperature. But when we pass a spark through a vapour giving us that red line we do not increase, but rather reduce, the intensity of the line, and we bring a great many lines into prominence which were not seen before, and those lines, I believe we are justified in saying, do exist among the Fraunhofer lines. In the same way we can colour the flame red with lithium, but the red line of lithium is not in the sun; but by passing a spark through lithium vapour we can intensify the line in the yellow and the line in the blue; and the line in the blue is undoubtedly among the Fraunhofer lines. Therefore it appears that we really can account for a great many of these variations in the solar spectrum by simply assuming that those lines which are absent represent molecular groupings so complex that there is no part of the sun where their absorption could be visibly produced, cold enough to allow them to exist.

Test supplied by the Lines strengthened in Spots and Flames and those seen in the Spectra of Two or more Substances

It has already been pointed out that these lines, which have been called basic lines, have been tested in two ways. In the first place, a list of lines had been prepared from Ångström's tables and Thalèn's tables, and then they had been discussed in connection with the bright lines seen by Young in his observations on Mount Sherman. The result was striking, inasmuch as of the 345 lines which were included by Young, only a small number of which were seen in spots and storms, 15 of the lines which were recorded as common to two substances by Thalèn, had been seen almost without exception, the only exception being in the case of some of the spots. The attack was then varied by taking 100 observations of sun-spots at Kensington, determining, without any reference to the basic nature of the lines at all, the 12 most widened lines in each spot which it was possible to observe; and then taking, side by side with these observations of the spots, 100 observations of flames from the rich store which has been recorded by Prof. Tacchini of Palermo. Then again, without reference to the basic character of the lines, to plot the lines down in each flame day by day.

As a reminder we may again refer to the diagram already given (Fig. 36). It will be remembered that the result was a very remarkable one. We found the lines of iron (we limited ourselves to iron) seen in the spots were few in number; that the lines of iron seen in the flames were still fewer in number, and moreover that the lines seen in the flames were not the lines seen in the spots. That was a result which might have been considered as very extraordinary if we had brought to it no other considerations than those with which we were conversant ten years ago when the work began.

What we have to do now, then, is to find what has been the result of this inquiry with regard to the basic nature of these lines. Have we, as a matter of fact, or have we not, in these most widened lines in spots, and the most brightened lines in flames, picked out those lines which are common to two substances. The facts are these:—We have, in the first horizon of the lower part of the accompanying map, the lines recorded by Ångström in his first memoir as common to two substances; the names of the two substances being given below. In the fourth horizon we have the observations of Thalèn made a few years after the observations of Angström. And in passing from Ångström to Thalèn we pass from the temperature of the arc to the temperature of the induction coil. Now it will be seen that Thalèn also gives us lines in some cases agreeing with Ångström's, in other cases extending the information given by him, and in order to make this work as complete as possible we have gone over this region with the arc as Ångström did, and with the induction coil as Thalèn did, only we have had the advantage probably of using a more powerful coil. In fact we have used two coils—one so arranged as to give us the maximum effect of tension, and the other the maximum effect of quantity. In the first place it will be seen there is a general agreement between the observations—an agreement marred only in appearance here and there by the fact that in some cases the lines are so near the position of air lines that it has been impossible to make the observation absolutely complete. In other cases the appearance of imperfection arises from the fact that lines which are not seen at the temperature of the arc begin to make their appearance at the temperature of the coil; so that in a case like *that* at wave-length 5017, for instance, where Ångström gives no line as common to two substances, yet Thalèn does. We find that both are right; that at the temperature of the electric arc that line does not appear in one substance or the other, while at the temperature both of the quantity and the intensity induction coil the line is certainly there. In Fig. 36 A represents Ångström's work, T Thalèn's, and L Q and L I my own work with the quantity and intensity coil.

What then is the total result? It is this—that every important line in the spots, every important line in the storms, has been picked up by this method, and in fact *the map of basic lines along this region is practically a map of the lines widened in spots and present in storms, and nothing else.* Now it may be said that result is interesting, and perhaps important, but that it deals only with a very limited part of the inquiry. That is perfectly true.

The spectrum of iron, and the spectra of other substances have however been attacked in other regions. It is unnecessary to go into many details, but the general result is the same; in other regions we have as in the old region an almost perfect coincidence between the lines most widened in spots, and the lines regarded as basic by previous observers.

So much then for the result in the case of iron, to which, although we have not absolutely limited our attention, we have to a very large extent confined it. This result may be expressed in rather a different way, and it will then be easy to see the extraordinary parallelism which goes on between two perfectly distinct sets of facts, first, the statement of the spectroscope that such and such a line is seen in the spectra of two or more substances, and then the statement of the telescope with the attached spectroscope that such and such a line is seen widened in spots or brightened in flames. Here we have the numbers for the two regions which I have already discussed the region from F to *b*, and from *b* towards D.

Iron

	F–*b*	*b*–548
Total number of lines	96 ...	67
Number in spots and flames	38 ...	41
Basic lines	15 ...	17
,, seen in ,, ,, ...	14 ...	15
,, not seen ,, ,, ...	1 ...	2

The total number of iron lines in the first case is 96. Of those 96 lines only 38, or less than half, are found in the spots and flames. When we go into the lower regions of the solar atmosphere, we leave in fact more than half of the iron lines on one side. Of these 96 lines 15 are found by other observers as well as myself to be common to two or more substances. Now comes the question, what is the behaviour of these common lines with reference to spots and storms? The table shows that among the lines seen in spots and storms fourteen of these basic lines are seen. It must be remembered that our records only give us day by day the results of the 12 most widened lines, and not of all the lines widened. In the next region the number of iron lines is somewhat less—67; 41 of these, or more than half, are picked out by spots and storms; Seventeen are basic; of the 17 basic ones 15 are seen in the spots and storms, and only two are lines that are not seen.

Now, we will turn to another substance, nickel, and there we see very much the same kind of thing at work. In nickel for the region F to *b* we have 20 lines recorded by Thalén.

Nickel.

	F–*b*
Total number of lines	20
Number in spots and flames	3
Basic	5
,, Seen	3
,, Not seen	2

Of these 20, 17 are dropped, abolished, when we come to observe the bright lines and the widened lines of nickel in the spots and storms—the 20 comes down to 3. Among the 20 lines 5 are found to be common to two substances. Of those 3 are seen in the flames, that is to say, every line of nickel seen in a spot or flame is common to two substances, and only 2 are visible in the 20 lines not affected by spots and storms. This is all the work of this nature which we need now consider, but it is not all the work that has been done. Neither my assistants nor myself, I am sure, have spared our attempts, nor ourselves, for the matter of that, in trying to get at the bottom of this matter, and the facts which have been here brought forward are typical of a much larger number of facts which have been observed. In the case of every part of the spectrum, in the case of every substance, the verdict is the same. We have the fact, that two things are going on exactly parallel to each other—first that some lines are common to two substances; next that the lines common to two substances are seen almost exclusively alone, both in the sun's spots and in the sun's flames. So that in addition to the fact that the hottest regions of the sun seem to simplify the spectra of the substances enormously, we have this result that the simpler the spectrum becomes, the more complex becomes the origin of the lines; by which I mean that in the ordinary solar spectrum there are a great many lines due to iron, and to nothing else; but the moment we come to the simpler spectrum yielded to us in the spots or the flames, then we have no more right to say that those lines belong to iron than that they belong to titanium, cerium, nickel, and other substances with which those lines are generally observed to be basic.

This, then, is a help towards the demonstration of the view which was first announced in the year 1874, that the line-spectra of bodies (we are dealing almost exclusively with line-spectra) are not produced by the vibration of similar molecules, but they probably represent to us the vibrations of a great number of simplifications brought about by the temperature employed to produce the incandescence of the vapours.

Can we go further than this? Here we must confess both our imperfect instrumental and mental means. We cannot talk of *absolute* coincidence because the next application of greater instrumental appliances may show a want of coincidence. On the other hand there may be reasons about which we know at present absolutely nothing which should make absolute coincidence impossible under the circumstances stated. The lines of the finer constituents of matter may be liable to the same process of shifting as that at work in compound bodies when the associated molecules are changed; but however this may be the fact remains, whatever the explanation may be, that the lines of the elementary bodies mass themselves in those parts of the spectrum occupied by the prominent lines in solar spots and storms.

J. Norman Lockyer

(*To be continued.*)

STATE MEDICINE[1]

FIRST: a few words on what may be called the general theory of our subject-matter. The term "State Medicine" corresponds to the supposition that, in certain cases, the Body-Politic will concern itself with the health-interests of the people—will act, or command, or deliberate, or inquire, with a view to the cure or the prevention of disease. Before any such supposition can be effectively realised, the science of medicine—that is to say, the exact knowledge of means by which disease may be prevented or cured—must have reached a certain stage of development; and unless the science be supposed common to all persons in the State, the existence of State medicine supposes a special class of persons whom the unskilled general public can identify as presumably possessing the required knowledge. Thus, given the class of experts to supply the required exact knowledge, the Body-Politic undertakes that, within the limits of its own constitutional analogies, it will make the knowledge useful to the community.

I have intimated that in State Medicine (just as in private medicine) the medical function may be exercised either in curing or in preventing disease; but practically these two departments of State Medicine are not of equal magnitude, nor are dealt with in quite the same spirit.

As regards curative medicine, modern Governments have in general found it needless to interfere in much detail in favour of persons who require medical treatment.

Larger and far more various than the action taken by the State with reference to the cure of disease is that which it takes in regard of prevention; and it is particularly of preventive medicine that I propose to speak. In its legal aspect it is represented by a considerable mass of statutes (nearly all of them enacted within the last thirty-five years), and by an army of administrative authorities and officers appointed to give effect to those enactments. I need not describe in detail the laws and administrative machinery to which I refer, but I may remind you of the largeness and variety of the rescope, even by quoting only the terms in which I was able, twelve years ago, to speak of the public health law of England: "It would, I think, be difficult to over-estimate, in one most important point of view, the progress which, during the last few years, has been made in sanitary legislation. The principles now affirmed in our statute-book are such as, if carried into full effect, would soon reduce to quite an insignificant amount our present very large proportions

[1] An Address delivered at the opening of the Section of Public Medicine, in the International Medical Association, by John Simon, C.B., F.R.S., D.C.L., LL.D.

of preventible disease. It is the almost completely expressed intention of our law that all such states of property and all such modes of personal action or inaction as may be of danger to the public health should be brought within scope of summary procedure and prevention. Large powers have been given to local authorities, and obligation expressly imposed on them, as regards their respective districts, to suppress all kinds of nuisance, and to provide all such works and establishments as the public health primarily requires; while auxiliary powers have been given, for more or less optional exercise, in matters deemed of less than primary importance to health; as for baths and wash-houses, common lodging-houses, labourers' lodging-houses, recreation-grounds, disinfection-places, hospitals, dead-houses, burial-grounds, &c. And in the interests of health the State has not only, as above, limited the freedom of persons and property in certain common respects, it has also intervened in many special relations. It has interfered between parent and child, not only in imposing limitation on industrial uses of children, but also to the extent of requiring that children shall not be left unvaccinated. It has interfered between employer and employed, to the extent of insisting, in the interest of the latter, that certain sanitary claims shall be fulfilled in all places of industrial occupation. It has interfered between vendor and purchaser; has put restrictions on the sale and purchase of poisons; has prohibited in certain cases certain commercial supplies of water; and has made it a public offence to sell adulterated food or drink or medicine, or to offer for sale any meat unfit for human food. Its care for the treatment of disease has not been unconditionally limited to treating at the public expense such sickness as may accompany destitution; it has provided that, in any sort of epidemic emergency, organised medical assistance, not peculiarly for paupers, may be required of local authorities; and, in the same spirit, it requires that vaccination at the public cost shall be given gratuitously to every claimant. The above survey might easily be extended by referring to statutes which are only of partial, or indirect, or subordinate interest to human health; but, such as it is, it shows beyond question that the Legislature regards the health of the people as an interest not less national than personal, and has intended to guard it with all practicable securities against trespasses, casualties, neglects, and frauds."[1] At the time when that description was written I unfortunately had to confess that the intentions of the Legislature were not carried into effect; for that the then existing laws (especially in respect of the local authorities which should give effect to them) were in a state of almost chaotic confusion and unworkability; but since that time an entirely new constitution of local authorities has been made, some thousands of additional officers have been appointed, and the general fabric of the law has been consolidated, and its powers in some respects extended and made more stringent, with a view to the better prevention of disease, so far as legal powers and facilities can attain that object.

Such being the very large contribution which the Body-Politic makes to the purposes of State Medicine in this country, let us next see how we of the medical profession stand in respect of the scientific contribution which we distinctively owe to the same great object.

In preventive, just as in curative, medicine, it occasionally happens that consequences more or less valuable result from some mere chance-hit of discovery; but except so far as this may sometimes (and but very rarely) happen, disease can only be prevented by those who have knowledge of its *causes*—knowledge which does not deserve to be called knowledge, unless in proportion as it is *conclusive and exact;* and thoroughly to investigate the causes and their mode of operation is the quite indispensable first step towards any scientific study of prevention. Essentially we know how to prevent, by having first learnt exactly how to cause. Therefore it is that preventive medicine has had almost no development until within these later times. The germinal thought of it may be traced in even the first days of our profession. The spirit in regard of which Hippocrates has been aptly called the Father of Medicine—the scientific spirit of observation and experiment, as distinguished from the spirit of priestcraft, was one which his medical writings equally showed in their preventive as in their curative relations; and when he, some twenty-three centuries ago, expounded to his contemporaries that pathology is a branch of the science of nature—that causes of disease are to be found in physical accidents of air and earth and water, and in quantities and qualities of food, and in personal habits of life, he (not without risk of being denounced for impiety) virtually proclaimed for all time the first principle of preventive medicine, and indicated to his followers a new line of departure for those who would most largely benefit mankind. His followers, however, have had their work to do. True knowledge of morbific causes could only come by very slow degrees, and as part of the development with which the physical and biological sciences have, little by little, with the labour of ages, been building themselves up; and so no wonder that, despite the lapse of time, even the most advanced of nations are hitherto but beginning to take true measure of the help which preventive medicine can render them.

Now what is the nature of that *study of causes* through which we may gradually arrive at counter-causing or prevention?

Addressing a skilled audience, I shall utter what to them is the merest commonplace when I say that, in the physical and biological sciences we acknowledge no other study of causes than that which consists in *experiment.* And the study of morbific causes is no exception to that rule: it is solely by means of experiment that we can hope so to learn the causes of disease as to become possessed of resources for preventing disease.

The experiments which give us our teaching with regard to the causes of disease are of two sorts: on the one hand we have the carefully pre-arranged and comparatively few experiments which are done by us in our pathological laboratories, and for the most part on other animals than man; on the other hand, we have the experiments which accident does for us, and, above all, the incalculably large amount of crude experiment which is popularly done by man on man under our present ordinary conditions of social life, and which gives us its results for our interpretation.

When I say that experiments of those two sorts are the sources from which we learn to know the causes of disease, I of course do not mean that the mental process by which an experiment becomes instructive to us is the same in regard of the two sorts of experiment. On the contrary, the ætiological problem (so long as it is a problem) is approached in the two cases from two opposite points of view; and the dynamical continuity of relation, which we call cause and effect, is traced, in the one case, from the one pole, and in the other case, from the other pole of the relation. In the one case, starting with knowledge of our own deliberately-prepared *cause,* our question is, What will be its effect? In the other case, starting from a certain *effect* presented to us, our question is, What has been its cause? But in the second case, just as in the first, when the question is answered, when the problem is solved, when the relation of cause-and-effect has been made clear, we recognise that the conjuring-power which has brought us our new knowledge is the power of a *performed experiment.*

Let me illustrate my argument by showing you the two processes at work in identical provinces of subject-matter.—What are the classical experiments to which we habitually refer when we think of guarding against the dangers of Asiatic cholera? On the one side there are the well-known *scientific* infection-experiments of Prof. Thiersch, and others following him, performed on a certain number of mice. On the other hand, there are the equally well-known *popular* experiments which, during our two cholera epidemics of 1848-9 and 1853-4, were performed on half a million of human beings, dwelling in the southern districts of London, by certain commercial companies which supplied those districts with water. Both the professor and the companies gave us valuable experimental teaching as to the manner in which cholera is spread. I need not state at length the facts of those experiments, probably known to all here, but may rather justify my parallel by referring to an ætiological question which will presently be discussed in our section.

It concerns the *causation of tubercle*—the most fatal by far of all the diseases to which the population of this country is subject. On that subject, for the last sixteen years, we have had a new era of knowledge. It was the great merit of a Frenchman, M. Villemin, that he, in 1865, first made us fully aware that tubercle is an infectious disease. He did this by certain *laboratory experiments* performed on other animals than man. He found that general and fatal tubercular infection of the animal was produced when he inoculated it subcutaneously with a little crude tubercular matter from the human subject. That first laboratory investigation of the subject has been followed most extensively by others; and the further experiments, while

[1] "Eleventh Report of the Medical Officer of the Privy Council," 1869, pp. 20, 21.

entirely confirming M. Villemin's discovery, have shown that subcutaneous inoculation is not the only mode by which the tubercular infection can be propagated. Dr. Tappeiner and others have shown that the same effect is produced on the animal if tubercular matter (such as the sputa of phthisical patients) be diffused in spray in the air which the animal breathes; and Prof. Gerlach of Hanover showed twelve years ago with regard to the bovine variety of tubercular disease (the perlsucht of the Germans), that its infection can be freely introduced through the stomach if bits of tubercular organs be given in the food, or if the healthy animal be fed with milk from the animal which has tubercle. That the communicability of tubercle from animal to animal is also being tested to an immense extent by *popular experiments* on the human subject, is what a moment's reflection will tell; and from that wide field of experiment I select one instance for illustration. I have every reason to believe that Prof. Gerlach's experiments on the communicability of tubercle by means of milk are very extensively parodied by commercial experiments on the human subject. I learn, on what I believe to be the highest authority in this country, that tubercle (in different degrees) is a malady which abounds among our cows; and that so long as the cow continues to give milk, no particular scruple seems to prevent a distribution of that milk for popular use. To the persons who consume that milk an important question as to the causability of tubercle is put in an experimental form. Whether they will become infected with tubercle is a question which the individual consumers do not stand forward to answer for themselves, like the animals of the laboratory experiments: but Dr. Creighton's lately-published book, entitled, "Bovine Tuberculosis in Man," and a paper in which I am glad to say he brings under notice of our section the very remarkable series of facts on which he grounds that startling title, seem to suggest a first instalment of answer in accordance with Prof. Gerlach's experimental finding.

The two sorts of experiment—the scientific and the popular—differ, as I have noted, in this particular: that the popular experiment is almost always done on man; the scientific almost always on some other animal. It is true that many memorable cases are on record, where members of our profession have deliberately given up their own persons to be experimented on by themselves or others for the better settlement of some question as to a process of disease; have deliberately tried, for instance, whether, in this way or in that, they could infect themselves with the poison of plague or of cholera; and as regards one such case which is in my mind, I think it not unlikely that the illustrious life of John Hunter was shortened by the experiments which he did on himself with the ignoble poison of syphilis. There have been cases, too, where criminals have been allowed to purchase exemption from capital or other punishment at the cost of allowing some painful or dangerous experiment to be performed on themselves. And cases are not absolutely unknown where unconsenting human beings have been subjected to that sort of experiment. But waiving such exceptions, the rule is, as I have said, that scientific experiments relating to causes of disease are performed on some animal which common opinion estimates as of lower importance than man. Now, as between man and brute, I would not wish to draw any distinction which persons outside this room might find invidious; but, assuming for the moment that man and brute are of exactly equal value, I would submit that, when the life of either man or brute is to be made merely instrumental to the establishment of a scientific truth, the use of the life should be economical. Let me, in that point of view, invite you to compare, or rather to contrast with one another, those two sorts of experiment from which we have to get our knowledge of the causes of disease. The commercial experiments which illustrated the dangerousness of sewage-polluted water-supplies cost many thousands of human lives; the scientific experiments which with infinitely more exactitude justified a presumption of dangerousness, cost the lives of a few dozen mice. So, again, with experiments as to the causation of tubercle:—judging from the information which I quoted to you, I should suppose that the human beings whose milk-supply on any given day includes milk from tubercular cows might be counted, in this country, in tens of thousands; but the scientific experiments which justify us in declaring such milk-supply to be highly dangerous to those who receive it were conclusive when they amounted to half-a-dozen. So far, then, as regards the mere getting of experimental knowledge, we must not, with a view to economy of life, be referred to popular, rather than scientific, experiment. And in the same point of view, it perhaps also deserves consideration that the popular experiments, though done on so large a scale, very often have in them sources of ambiguity which lessen their usefulness for teaching.

Let me now briefly refer to the fact that, during the last quarter of a century, all practical medicine (curative as well as preventive) has been undergoing a process of transfiguration under the influence of laboratory experiments on living things. The progress which has been made from conditions of vagueness to conditions of exactitude has, in many respects, been greater in these twenty-five years than in the twenty-five centuries which preceded them; and with this increase of insight, due almost entirely to scientific experiment, the practical resources of our art, for present and future good to the world, have had, or will have, commensurate increase. Especially in those parts of pathology which make the foundation of preventive medicine, scientific experiment in these years has been opening larger and larger vistas of hope; and more and more clearly, as year succeeds year, we see that the time in which we are is fuller of practical promise than any of the ages which have preceded it. Of course, I cannot illustrate this at length, but some little attempt at illustration I would fain make.

First, let us glance at our map. When we generalise very broadly the various causes of death (so far as hitherto intelligible to us) we see them as under two great heads, respectively autopathic and exopathic. On the one hand, there is the original and inherited condition under which to every man born there is normally assigned eventual old age and death, so that, sooner or later, he "runs down" like the wound-up watch with its ended chain; and, as morbidities under this type, there are those various original peculiarities of constitution which make certain individual tenures of life shorter than the average, and kill by way of premature old age of the entire body, or (more generally) by quasi-senile failure of particular organs. On the other hand, as a second great mass of death-causing influence, we see the various interferences which come from outside; acts of mechanical violence, for instance, and all the many varieties of external morbific influence which can prevent the individual life from completing its normal course.

As regards cases of the first class—cases where the original conditions of life and development are such as to involve premature death (which in any such case will commonly show itself as a fault in particular lines of hereditary succession)—the problem for preventive medicine to solve is, by what cross-breeding or other treatment we may convert a short-lived and morbid into a long-lived and healthy stock; and this, at least as regards the human race, has, I regret to say, hardly yet become a practical question. But, as regards cases of the second class, evidently the various extrinsic interferences which shorten life have to be avoided or resisted, each according to its kind; and here it is that the scientific experimenters of late years have been giving us almost daily increments of knowledge.

Two early instances, vastly important in themselves, though of a comparatively crude kind, I have already mentioned; and I now wish to glance at some illustrations of the immense scope and the marvellous exactitude of the newer work.

The invaluable studies of M. Pasteur, beginning in the facts of fermentation and putrefaction, and thence extending to the facts of infectious disease in the animal body, where M. Chauveau's demonstration of the particulate nature of certain contagia came to assist them—they, I say, partly in themselves, and partly in respect of kindred labours which they have excited others to undertake, have introduced us to a new world of strange knowledge. We have learnt, as regards those diseases of the animal body which are due to various kinds of external cause, that probably all the most largely fatal of them (impossible yet to say how many) represent but one single kind of cause, and respectively depend on invasions of the animal body by some rapidly self-multiplying form of alien life. This doctrine, which scientific experiment initiated, has, for the last dozen years, been extending and confirming itself by further experiment. As soon as the doctrine began to seem probable, science saw that, should it prove true, it must have the most important corollaries. If the cause of an infecting human disease is a self-multiplying germ from the outside world, the habits of that living enemy of ours can be studied in its outside relations. It becomes an object of common natural history, it has biological affinities and analogies. We can cultivate it in test-tubes in our laboratories, as the gardener would cultivate a rose or an apple, and we can see

what agrees and what disagrees with its life. And then, as the next and immeasurably most important stage, where nothing but experiment on the living body will help us, we can try whether perhaps any of our modifications of its life have made it of weaker power in relation to the living bodies which it invades, or whether, through our more intimate knowledge of its vital affinities, we can artificially give to bodies which it would invade, a partial or complete protection against it. Such, at first blush, were the obvious possibilities of research which the new doctrine of infectious disease suggested to the mind of the pathologist; and never since the profession of medicine has existed, had a field of such promise been before it. The promise has not been belied. A host of diseases has been worked at in such lines as I just now indicated, and with many of them important progress has been made.

It would be impossible for me even to name a twentieth part of the investigations which have been more or less successful. As regards some which have most struck me, I pass with but a word Dr. Klein's investigation of the pneumo-enteritis of swine; Prof. Cohn's and Dr. Koch's and Dr. Buchner's respective contributions to the natural history of the anthrax bacillus; Dr. Bollinger's recognition of the microphytic origin of an important cancroid disease of horned cattle, with Dr. Johne's illustration of the inoculability of this disease; the research by Drs. Klebs and Tommasi-Crudeli into the intimate cause of marsh-malaria; and, not least, the demonstration (as it appears to be) which Dr. Grawitz has recently published, that some of the commonest and most innocent of our domestic microphytes can be changed by artificial culture into agents of deadly infectiveness. I pass these and others, in order that I may more particularly speak of some which have already shown themselves practically useful; for in respect of some of them the time has already come when abstract scientific knowledge is passing into preventive and curative knowledge.

First, and not in a spirit of national partiality, I will mention the application which M. Pasteur's doctrine has received at the hands of Mr. Lister, with regard to the antiseptic treatment of wounds: an application which, enforced and illustrated at every turn by Mr. Lister's own eminent skill as an experimentalist, has been confirmation as well as application of the parent doctrine; and the beneficent uses of which, in giving comparative safety to the most formidable surgical operations, and in immensely facilitating recovery from the most dangerous forms of local injury, are recognised—I think I may say, by the grateful common consent of our profession in all countries, to be among the highest triumphs of preventive medicine.

Secondly, out of the experimental studies of anthrax—chiefly out of those of Dr. Sanderson and Mr. Duguid in this country, and those of Dr. Buchner in Germany and M. Toussaint in France, has grown a knowledge of various ways in which the contagion of that dreadful disease can be so mitigated that an animal inoculated with it, instead of incurring almost certain death, shall have no serious illness; and the further knowledge has been gained that the animal submitted to that artificial procedure is thereby more or less secured against subsequent liability to the disease. In other words, with regard to that disease, an infliction which sometimes spreads to man from his domestic animals, and one which in some parts of Europe is of serious consequence to agricultural interests, as well as to animal life, the later experimenters—of whom I may particularly name M. Toussaint and our countryman, Prof. Greenfield, seem to be giving to the animal kingdom, and to the farmers, the same sort of boon as that which Jenner gave to mankind when he taught men the use of vaccination. Quite recently, our great leader, M. Pasteur, seems to have made, by new experiments, still further progress in the mitigation of anthrax.

Thirdly, a similar discovery has been made by M. Pasteur, with reference to the contagium of a very fatal poultry disease, known by the name of fowl's cholera; he has learnt to mitigate that contagium to a degree, in which, if fowls be inoculated with it, they will suffer no serious ailment; and he has found that fowls so inoculated (or, as he, in honour of Jenner, would say, "fowls so vaccinated") are proof against future attacks of the disease.

Fourthly, Prof. Semmer of Dorpat, through experiments done under his direction by Dr. Krajewski, has made a similar discovery in regard of the infection of septicæmia; has found, namely, that by treatment like that with which M. Toussaint mitigates the contagium of splenic fever, he can bring the most virulent septic contagium into a state in which it shall be mild enough to serve for harmless inoculations; which inoculations, when performed, shall be protective against future infections.

Finally, in a different direction of experimental work, let me name the recent most admirable research which Dr. Schüller of Greifswald has made, nominally in respect of certain surgical affections of joints, but in reality extending to the inmost pathology and therapeutics of all tubercular and scrofulous affections. A knowledge of the fatal infectiveness of crude tubercular matter had been given (as I before said) by Villemin and those who followed him; and Prof. Klebs, four years ago, declared the infective quality to be due to the presence of a microphyte (micrococcus), which he had succeeded in separating from the rest of the matter by successive acts of cultivation in fluids of inorganic origin. Dr. Schüller solidly settles, and widely extends, that teaching. According to his apparently quite unquestionable observations and experiments, the micrococcus which characterises tubercle characterises also certain affections popularly called "scrofulous"—namely, "scrofulous" synovial membrane, "scrofulous" lymph-glands, and lupus: so that these diseases may be defined as essentially tubercular, and that inoculation with matter from any of them, or with a cultivation-fluid in which the micrococcus from any of them has been cultivated, will infect with general tuberculosis. The rapid multiplication of the tubercle-micrococcus in the blood and tissues of any inoculated animal can be verified both by microscopical observation, and by inoculative experiment; and an extremely interesting part of the research, in explanation of certain of our human joint-diseases, is the demonstration that if in the inoculated animal a joint is experimentally injured, that joint at once becomes a place of preferential resort to the micrococcus which is multiplying in the blood, and becomes consequently a special or exclusive seat of characteristic tubercular changes. Even thus far the practical interest of Dr. Schüller's book is such as it would not be easy to overstate, but still greater interest attaches to the last chapter of the book, in which, confidently resting on the pathological facts which I have quoted, he makes proposals for the treatment of tubercle on the basis of its microphytic origin, and shows the successful result of such treatment as he has hitherto tried, from that basis, on animals artificially infected by him.

I venture to say that in the records of human industry it would be impossible to point to work of more promise to the world than these various contributions to the knowledge of disease, and of its cure and prevention; and they are contributions which from the nature of the case have come, and could only have come, from the performance of experiments on living animals.

At this most productive epoch in the growth of medical science, our English studies have been interrupted. An Act of Parliament, passed five years ago under the title of the Cruelty to Animals Act, has made it difficult or impossible for scientific observers any longer to follow in this country any such courses of experiment as those which of late years, at the cost of relatively insignificant quantities of brute suffering, have tended to create an infinity of new resources of relief for the sufferings both of brute and man. The Act does not in express terms interdict all performance of such courses of experiment: it nominally allows them to be done under a variety of limited licences which may be granted by a Principal Secretary of State; but the limitations under which these licences are granted, and the trouble, delay, and friction which necessarily to some extent, and, in fact, often to an intolerable extent, attend the obtaining of any one of them, are practically little better than prohibition.

The Act apparently contemplates, as the chief subjects of its operation, an imaginary class of unqualified persons, who, with no legitimate relation to scientific research, would, under pretence of such research, torture, and (it is supposed) take pleasure in torturing, live animals; and against this devilish class of persons the Act is very indulgently framed: for, instead of expressly refusing licence to unqualified persons, and perhaps hinting to such of them as would do wilful cruelty under pretence of study that the lash and the treadmill are for such scoundrels—instead of this, I say, the Act virtually confounds together that imaginary class of unqualified and cruel persons, and, on the other hand, our professional class of *bonâ fide* scientific investigators, on whom the progress of medicine depends, and whose names are sufficient security for their conduct. What is counted good for the one class is also counted good for the other. The law will trust no licensed experimenter farther than

it can provide for his being minutely watched and regulated by the Secretary of State: and in respect of the details of experimental procedure, the supervision of that high political officer is substituted for the discretion and conscience of the scientific investigator.

Consider for a moment what this means in regard of the members of our profession whom it affects. Contrast with it the almost unbounded trust with which the world, from time immemorial, has regarded the character of our profession. Consider the relation of inmost confidence in which members of our profession in every corner of the kingdom are admitted to share in the sanctities and tendernesses of domestic life. Consider our immense daily responsibilities of human life and death. Consider that there is not a member of our profession to whom the law does not allow discretion that, in certain difficulties of childbirth, he shall judge whether he will kill the child to save the mother. And in contrast with all this, is it to be seriously maintained that society cannot trust us with dogs and cats? that our foremost workers—(for it is essentially they who are affected)—cannot be trusted to behave honestly towards their brute fellow-creatures, unless they be regulated and inspected under a special law in much the same prevenient spirit as if they were prostitutes under the Contagious Diseases Act?

I have reason to believe that, if that Act continues on the statute-book, one of two results will follow. Experiments, indispensably necessary for the growth of medical science in relation to the cure and prevention of disease, will cease, or almost cease, to be done in this country; or, as the alternative to this, persons who desire to advance the science of their profession, will be tempted to clandestinely ignore the law and to run their chance, if the worst comes to the worst, of having to try conclusions with the common informer.

Let me illustrate this by two personal references: I have already mentioned Prof. Lister as an experimenter, whose name is now classical wherever science has reached, and whose work has been of signal advantage to mankind. Last autumn Mr. Lister wished to do some experiments in extension of the particular branch of knowledge with which his name is identified, and at a point which he considered of extreme importance in surgical pathology. He found he must either abandon his investigation or must conduct it in a foreign country, and in his zeal for science he chose the latter course. His experiments (which had to be on large animals) were done at the Veterinary College of Toulouse; and in stating this fact in a letter, from which I quote, Mr. Lister added that "even with reference to small animals, the working of the Act is so vexatious as to be practically prohibitory of experiments by a private practitioner like myself, unless he chooses to incur the risk of transgressing the law." A second name which I have mentioned is that of Prof. Greenfield, who has so highly distinguished himself in developing, by means of experiments, the preventive medicine of splenic fever. Dr. Greenfield, in order to perform his inoculation-experiments, had of course to become a licence-holder under the Act; and his experience of the hindrances which attach to that position is expressed to me in the following terms: "It is my deliberate conviction, as a result of my experience, that these hindrances and obstacles are so numerous and so great as to constitute a most serious bar to the investigation of disease, and even of such remedial measures as would by common consent be for the direct benefit of the animals experimented upon. When to this is added all the annoyance and opprobrium which are the lot of investigators, it is to be wondered at that any one should submit to be licensed." Dr. Greenfield's experimental operations consisted only in inoculating the virus of animal diseases, and he says: "I have not been engaged in other investigations for the simple reason that, with the present restrictions and the difficulty in obtaining a licence, I regard it as almost hopeless to attempt any useful work of the kind in this country."

As I feel sure that the Act must at no distant time be reconsidered by the Legislature, and as I also very strongly feel that, quite apart from any question of legal enactments, there is the question of moral right or wrong to be considered in the matter, I would beg you to allow me to make my own public confession of faith (from which I dare say yours will not much differ) in that extremely important matter of controversy.

The question being whether medical science can rightly use living animals as subjects for experiments which may be painful, and even, in exceptional cases, very painful to them, the answer may be sought in either of two directions: 1. What says the voice of the experimenter's own conscience? and 2. What says the standard of common contemporary conduct in analogous cases?

As regards the first, if I may take the liberty of expressing my own feeling, I would say this. I do not in any degree regard it as matter of indifference that, in certain cases, by my own hand or by that of some one acting for me, I must inflict death or pain on any living thing. I, on the contrary, think of it with true compunction; but I think of it as good or bad according to the end which it subserves. Where I see my way to acquire, at that painful cost, the kind of exact knowledge which, either in itself or in contribution to our common stock, will promote the cure or prevention of disease in the race to which the animal belongs, or in the animal kingdom generally, or (above all) in the race of man, I no more flinch from what then seems to me a professional duty, though a painful one, than I would, in the days before chloroform, have shrunk from the cries of a child whom I had to cut for stone. If, in a case of the latter sort, the surgeon nerves himself to his work by the conviction of an indispensable usefulness in what he has to do, so does the pathologist in his, and surely in a much larger sense. The agitated parent of the child might sometimes be tempted to say: "Forbear giving this cruel pain; let the poor little sufferer die"; but the surgeon's reply would have comforted her. And so with the physiological experimenter: except that he, instead of looking at one individual life to be saved, is looking at a race or at many races, and reflects how, in respect of some grievous physical misery, the whole of them, in all their multitudinous successions, may be redeemed through the suffering of the few. This is my personal view of the abstract right or wrong in the question. I state it because, in matters of right and wrong, no man ought to shelter himself behind authority. I believe I may add that if it, or something very like it, had not for centuries been the general view of the medical profession, our professional knowledge would probably be standing in this present age about where it stood in the days of the Plantagenets. Of Harvey and Hunter and Bele, we well know that such was the view on which they acted in rendering their immortal services to mankind; and I am not aware that any man, whose opinion really counts in matters of medical science, would express any material dissent from it.

The second standard to which I referred was that of the common conduct of men in *analogous* cases. I pointedly say "analogous," rather than "similar," because common life does not in fact give cases which, properly speaking, are "similar" to ours. But what, I ask, is the common *principle* of behaviour of civilised man towards the so-called lower animals? He in every respect subordinates their lives to his own. If he thinks he can get an advantage to himself by killing or painfully mutilating an animal, he does so with apparently no hesitation. See, for one instance, the sexual mutilations which are inflicted on all but a small minority of most kinds of domestic animals, and, as regards some kinds, on many of the females. When I appeared as a witness six years ago before the Royal Commission which was considering the question of our experiments, I particularly endeavoured to draw their attention to this view of the case; and in one of my answers (No. 1491) I entered on it more fully than would be suitable to the present occasion.

Thus, either way, whether I look to what I may call the general conscience of the medical profession, or look to the principles by which men in general govern their conduct towards the brute creation, nowhere do I see fair ground on which exception from outside can be taken to a limited, a strictly economical, use of animal life for purposes of scientific experiment.

No doubt there can be found, outside the medical profession, excellent persons, and plenty of them, whose first inclination would be to dissent from that position of ours; and some such persons have (as I think, hastily) given public utterance to such first impressions, and done their best to promote legislation against us. Among names which I see identified with opinions different from ours, are some for which I have deep respect. Particularly of one such man, whom I have the honour to know, I think it may be truly said that his own whole life has been one of practical beneficence, and I would not willingly incur the censure of any such man. But even to him I would fearlessly say, that I think he has not done justice to the case of our profession. To him, and such as him, I would confidently appeal to reconsider their first impressions. On him, and such as him, I would urge that the practice of scientific experimentation on

living animals is but an infinitesimally small application of the licence which common life claims for itself in regard of animals; and I would challenge such men to examine, with strict impartiality, what are their own responsibilities, direct and indirect, in regard of the infliction of pain on living animals.

I protest against any man's applying to this extremely important question a purely arbitrary standard of right or wrong. Those who pronounce judgment on their neighbours must be prepared to state the principle on which they judge. "Compound for sins you are inclined to, by damning those you have no mind to," is the Pharisee's easy-going formula. Where would life be if that were generally accepted? Suppose a *genus* of action; let men draw an arbitrary line across it—a line prescribed by no better rule than that which governed the lady's dislike to Dr. Fell; let them affix a nickname of praise to all on one side of the line, and a nickname of dispraise to all on the other: truly we should thus have the readiest of royal roads to unlimited mutual persecution.

And I protest against a standard of right and wrong being fixed for us on grounds which are merely sentimental. In certain circles of society, at the present time, æsthetics count for all in all; and an emotion against what they are pleased to call "vivisection" answers their purpose of the moment as well as any other little emotion. With such sections of society, our profession cannot seriously argue. Our own verb of life is *ἐργάζεσθαι*, not *αἰσθάνεσθαι*. We have to think of usefulness to man. And to us, according to our standard of right and wrong, perhaps those lackadaisical æsthetics may seem but a feeble form of sensuality.

Of the mere screamers and agitation-mongers who, happy in their hysterics or their hire, go about day by day calumniating our profession and trying to stir up against it the prejudices and passions of the ignorant, I have only to express my contempt.

I regret to have had to speak at so much length of the heavy cloud which at present hangs over the study of scientific medicine in England, and which, in my opinion, is likely to be of specially disastrous effect on the progress of preventive medicine. As a very old public servant in that cause, I should indeed grieve to see it brought to a stand-still for want of the scientific nurture which, in truth, is its very basis of life; and, speaking publicly of the danger on this occasion, I have hoped that the occasion may give importance to what I say.

And now, gentlemen, from contemplating that cloud, which happily is but local, and which perhaps may be but temporary, I gladly turn to skies which have no cloud. If there exist in the social organism any function whatsoever for which development and eventual triumph may be foretold, surely it is that of State Medicine. Of the two great factors concerned in it—the two strong powers which within our own time have converged to make it the reality which it is—the growth of science on the one hand, and the growing stress of common humanity on the other, neither one is likely to fail. Of our science it is needless to say that it will grow. To the science of nature indeed is allotted that one incomparable human day which knows no sunset. In the pure light of its ever-present daybreak, individual workers will pass away, generations will change, but the studies of Nature, and, above all, the gathering of such knowledge as can lessen man's physical difficulties and sufferings, will surely grow from age to age, and, as on Proserpina's sacred tree, one golden fruit will follow another: "simili frondescet virga metallo." And no less also in the other direction, the auguries are wholly for our cause. Popular education is gradually making its way, and it will grow to be a force on our side. Masses of mankind that now have to be humbly pleaded for by others, will then be strong to speak for themselves. Physical interests, now but little understood, will then be within grasp of all men's apprehension. Not only will health be recognised at its true value, and its elementary requirements be regarded, but also the frauds and villanies which are now committed against it will have become intelligible to the common mind; and the workman of the future will strike against being cheated in health as he would now strike against being cheated in wages. As such times come to the world, the science and the profession which care for man as man will get to be better appreciated than now. And in proportion as an educated people grows to become Body-Politic, State Medicine will be seen to represent the true ideal of Government-action which sets its standard of success in the "greatest happiness of the greatest number."

OUR ASTRONOMICAL COLUMN

THE GREAT COMET OF 1881.—The observations of this body in both hemispheres from its discovery on May 22 by Mr. Tebbutt at Windsor, N.S.W., to the end of last month, are closely represented by a parabolic orbit. The intensity of light is now rapidly going off, and if any decided deviation from the parabola is established it can only be through the later observations in these latitudes. It is therefore important for the theory of the comet that the larger instruments in our observatories should be brought to bear upon the accurate determinations of position, and that this should be continued as long as practicable. The following ephemeris for Greenwich midnight is calculated from elements, which are likely to give the comet's places pretty closely:—

	Right Ascension.			Declination.			Log. Distance from	
	h.	m.	s.	°	′		Earth.	Sun.
August 20 ...	14	31	0 ...	+77	19·6	...	0·1206 ...	0·1501
22 ...		38	10 ...	77	3·0			
24 ...		45	22 ...	76	47·1	...	0·1376 ...	0·1672
26 ...		52	36 ...	76	31·9			
28 ...	14	59	52 ...	76	17·2	...	0·1532 ...	0·1837
30 ...	15	7	10 ...	76	3·2			
Sept. 1 ...		14	31 ...	75	49·2	...	0·1676 ...	0·1995
3 ...		21	54 ...	75	35·7			
5 ...		29	18 ...	75	22·4	...	0·1810 ...	0·2148
7 ...		36	46 ...	75	9·3			
9 ...		44	16 ...	74	56·3	...	0·1934 ...	0·2295
11 ...		51	51 ...	74	43·4			
13 ...	15	59	29 ...	74	30·8	...	0·2050 ...	0·2436
15 ...	16	7	11 ...	74	18·1			
17 ...		14	57 ...	74	5·4	...	0·2160 ...	0·2572
19 ...		22	47 ...	73	52·6			
21 ...		30	42 ...	73	39·7	...	0·2264 ...	0·2704
23 ...	16	38	41 ...	+73	26·7			

The intensity of light on September 23 will be only one-third of that on August 20.

Dr. B. A. Gould has published in pamphlet-form an account of the Cordoba observations of this comet, with particular reference to his observations of June 11, to which we referred last week. We give his conclusions respecting the object seen that evening in his own words:—"La latitud considerable presta poca probabilidad á la hipótesis de que esta estrella haya sido un planeta interior. El movimiento relativo en declinacion, y la falta de cualquier objeto visible de la misma clase en la vecindad del cometa el dia siguiente, no parecen admitir la suposicion que el cometa se hubiera dividido como el de Biela. El brillo que se necesitaba, para que fuese visible la estrella en aquel momento y aquella posicion, indica una magnitud no inferior á la tercera.

"Esta observacion tambien tiene que esperar su solucion en lo futuro, y tal vez solo despues de muchos años."

SCHÄBERLE'S COMET.—According to M. Bigourdan's elements, the position of this comet at Berlin midnight on August 23 will be in R.A. 11h. 42·5m., Decl. +40° 34′, and at the same hour on August 25 in R.A. 12h. 16·0m., Decl. +34° 14′, and the intensity of light will be at a maximum between these dates. It may be observable in the other hemisphere for some weeks after perihelion passage.

THE COMPANION OF SIRIUS.—Prof. Colbert of the Dearborn Observatory, Chicago, has calculated the following orbit of the companion to Sirius:—Apastron passage, 1867·0, position of node, 42°·4; node to periastron in the direction of the star's (retrograde) motion, 133°; inclination, 57°·1; eccentricity, 0·58; semi-axis major, 8″·41; period, 49·6 years. These elements give, for 1881·2: angle of position, 45°·6; distance, 9″·9; and for 1882·2, position 43°·1; distance, 9″·5. For 1890·2 the position is 322°·2; distance, 2″·2; and the distance is near its minimum.

SCIENTIFIC SERIALS

The Journal of Anatomy and Physiology, vol. xv. Part IV. July, 1881, contains: On the ovary in incipient cystic disease, by Dr. V. D. Harris and A. Doran (Plate 23).—The anatomy of the Koala (*Phascolarctos cinereus*), by Dr. A. H. Young.—On the lymphatics of the pancreas, by Drs. George and F. Elizabeth Hoggan (Plate 24).—A case of primary cancer of the femur, by R. Maguire (Plate 25).—A case of chronic lobar pneumonia, by

Thomas Harris.—A contribution to the pathological anatomy of primary lateral sclerosis (sclerosis of the pyramidal tracts), by Dr. Dreschfeld (Plate 26).—On the form and proportions of a fœtal Indian elephant, by Prof. Turner (Plate 27).—On the femoral artery in apes, by Dr. J. Macdonald Brown.—The brain and nervous system: a summary and a review, by Robert Garner.—Index to vol. xv.

THE recent numbers of *Trimen's Journal of Botany* (217–223) contain quite the average number of articles of interest, relating both to British and to foreign botany.—H. and J. Groves describe *Chara obtusa*, a species new to Britain.—Dr. Vines summarises the existing literature on the very difficult and intricate subject of the morphology of the Scorpioid Cyme, referring especially to the confusion resulting from the difference in the use between Continental and English writers of the terms "helicoid" and "scorpioid."—Prof. Dickson gives a very interesting account of the morphology of the pitcher of *Cephalotus folliculatis*, illustrated by two plates. His conclusions on its structure are thus summarised:—"1. That the pitcher results from a calceolate pouching of the leaf-blade from the upper surface. 2. That the apex of the leaf is on the far side of the pitcher-orifice from the main axis and from the lid, and is probably represented by the tip of the middle dorsal wing. 3. That the pitcher-lid represents an outgrowth or excrescence from the upper leaf-surface." Mr. C. B. Clarke and Dr. Hance continue their descriptive papers, the former relating chiefly to Indian, the latter to Chinese botany, and including the description of many new species. Among the more important of Mr. Clarke's contributions is a complete review of the order Commelinaceæ, in which are comprised 307 species (including the common *Tradescantia virginica*, or Virginian spider-wort of our gardens), distributed over twenty-six genera. These are placed by Mr. Clarke in three tribes—the Polliceæ (26 species), Commelineæ (144 species), and Tradescantieæ, which includes nineteen out of the twenty-six genera.

THOUGH the recent numbers (41, 42) of the *Scottish Naturalist* contain no article calling for special remark, this quarterly fully maintains the character which it has already acquired under the editorship of Dr. Buchanan White.

THE *American Naturalist*, July, 1881, contains: On the origin and descent of the human brain, by S. V. Clevenger.—On the eastern snow bird, by Samuel Lockwood.—On bacteria as a cause of disease in plants, by T. J. Burrill.—Record of American carcinology for 1880, by J. S. Kingsley.—Aboriginal stone-drilling, by Charles Rau.—On the effects of impacts and strains on the feet of mammalia, by E. D. Cope.

IN the last number of the *Bulletin* of the Torrey Botanical Club which has reached us are two interesting articles. Mr. F. Wolle described several freshwater algæ new to the flora of the United States, several of them being previously undescribed. These are *Synechococcus racemosus*, *Calothrix Hosfordii*, and *C. laculosa*. Prof. C. E. Bessey describes and figures a simple dendrometer for measuring the height of trees.

Annalen der Physik und Chemie, No. 6.—Determination of the specific gravity of distilled mercury at 0°, and the disturbing reactive dilatations of the glass therewith connected, by P. Volkmann.—Researches on sound-strength, by A. Oberbeck.—On the quantity of electricity furnished by an influence-machine of the second kind, and its relation to moisture, by E. Riecké.—On the distribution of electricity on the surface of moved conductors, by H. R. Hertz.—On Herr Exner's experiments with regard to the theory of Volta's fundamental experiments, by V. A. Julius.—The determination of the transference-numbers of the ions for lithium and carbonic acid compounds, by J. Kuschel.—On the galvanic behaviour of carbon, by H. Muraoka.—Remarks on Herr Warburg's paper, on some actions of magnetic coercitive force, by C. Fromme.—The intensity of the horizontal terrestrial magnetic force for Göttingen in 1880, with the secular variation of the same, by K. Schering.—On a new volumenometer, by A. Paalzow.—On the oxygen spectrum, by A. Paalzow and H. W. Vogel.—The photometry of the Fraunhofer lines, by K. Vierordt.—A polarisation-apparatus of platino-cyanide of magnesium, by E. Lommel.—On the law of dispersion, by the same.—Researches on the height of the atmosphere, &c. (continued), by A. Ritter.—On the absolute size of gas-molecules, by E. Dorn.—Remarks on Herr Besselhagen's paper on a new form of the Töpler mercury air-pump, by F. Neesen.

THE *Nuovo Giornale Botanico Italiano* for April contains an article by A. Piccone on the cause of the disease which was so destructive to the chestnut trees in the province of Genoa in the year 1880, and which was previously obscure. He claims to have established that it is due to the attacks of a parasitic fungus, *Septoria castaneæ*, which attacks the branches and leaves, but the reproductive organs of which he has been unable to detect. Its extraordinary development during that year appeared to be due to the rainy character of the summer. Fitzgerald and Bottini's article on the bryology of the valleys of the rivers Secchio and Magra is accompanied by a valuable coloured map showing the nature of the soil in the district bordering the western coast of the peninsula stretching from near the Gulf of Spezzia to Lucca.

Zeitschrift für wissenschaftliche Zoologie, Bd. 35, Heft 4, June 14, 1881, contains: On the minute structure of the stigmata in the insects, by O. Krancher (plates 28 and 29).—A revision of the species of Holothuroids described by Prof. Brandt from Mertens' collection, by Dr. Hubert Ludwig.—Contribution to a knowledge of the Hydrachnid genus Midea of Bruzelius, by F. Könike (plate 30).—A revision of the Hydrachnids described by H. Lebert from the Lake of Geneva, by F. Könike.—Contribution to a knowledge of the Psorospermeæ of fish, by Prof. O. Bütschli (plate 31).—Studies on the Bopyridæ, by Prof. R. Kossmann (plates 32 to 35).

Revue Internationale des Sciences Biologiques, June 15.—Examination of vision from the stand-point of general medicine (concluded), by M. Charpentier.—Insane conceptions, their mechanism and diagnostic character, by M. Spitzka.

Revue Internationale des Sciences biologiques, July, 1881, contains:—Metallotherapy, by Dr. L. H. Petit.—Protoplasm considered as the basis of animal and vegetable life, by Prof. Hanstein.—The multiplication, colonisation, and encystment of the rhizopods, a review by Dr. Bütschli.—On the coloration of living protoplasm by Bismarck Brown, by L. F. Henneguy.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, August 3.—R. Meldola, F.C.S., vice-president, in the chair.—Miss E. A. Ormerod exhibited some *Coleoptera* and *Hemiptera* from Port Elizabeth, South Africa.—Mr. E. A. Fitch exhibited an ear of wheat infested by *Siphonophora granarii*, every specimen of which was attacked by a parasite belonging to the genera *Allotria* or *Aphidius*.—Papers read: Mr. A. H. Swinton, on the oviposition of *Iodis vernaria*.—Prof. Westwood, description of a new genus of Hymenopterous insects (*Dyscolesthes*) from Chili.—Mr. A. G. Butler, descriptions of new genera and species of *Lepidoptera* from Japan.—Mr. R. Trimen, on some new species of *Rhopalocera* from Southern Africa.—Mr. C. O. Waterhouse, descriptions of new Longicorn *Coleoptera* from India.—Mr. W. L. Distant, descriptions of some new neotropical *Pentatomidæ* and *Coreidæ*, and of the female of *Morpho Adonis*, Cram.

PAPIN

Dr. Ernst Gerland's Life and Letters of Papin. (*Leibnizens und Huygens' Briefwechsel mit Papin, nebst der Biographie Papin's*, von Dr. Ernst Gerland. Berlin, 1881.)

AT a time when Britons have just been celebrating the centenary of Stephenson a glance at the life and works of one who in a much more accurate sense was *the inventor* of the steam-engine may not be amiss. Denis Papin, whose life and letters now appear from the editorial pen of Dr. Ernst Gerland, was born at Blois in 1647. In 1661 or 1662 he proceeded to the study of medicine at the University of Angers, and, receiving his degree in 1669, he appears to have intended to settle down to a physician's life in that city. Why this course was not fulfilled is not known; but we find him in 1674 at Paris, where also he had made the acquaintance of Huygens, with whom he was engaged in experimenting with the newly-discovered air-pump, an account of which was published in that year at Paris under the title of "Expériences du Vuide." The *Philosophical Transactions* of our Royal Society for the following year (1675) were enriched by no fewer than five papers on the same subject by Huygens and Papin jointly. In Paris also Papin met Leibniz, who sojourned there from 1672 to 1676. His acquaintance with Leibniz was however interrupted, for, very shortly after the publication of his "Expériences," he crossed the Channel to England, led, as Boyle tells us, by some hope that here he might procure a situation accordant to his genius. In London he assisted Boyle in his laboratory and with his writings, and shortly afterwards introduced into the air-pump the further improvement of making it with double barrels, and replacing the turncock hitherto used by the two valves. A little later he produced another instrument, the condensing pump, and in 1680, on Boyle's nomination, he was admitted to the distinction of Fellowship in the Royal Society. That honour he repaid in the following year by communicating to the Society his famous invention of "A new Digester or Engine for Softening Bones," in which instrument—now so universally known—he applied as it seems for the first time the now common device of a safety-valve. For that year and the next he devoted himself to experiments with the digester and its various applications. Then he received an invitation to proceed to Venice to take part in the work of the Accademia di Scienze Filosofiche e Matematice, then newly founded, in imitation of the learned societies of Rome, Florence, Paris, and London. Here he appears to have remained nearly two years, and early in 1684 we find him back again in London, where, on April 2, he was elected by the Royal Society as their "temporary curator of experiments," at a salary of 30*l.* per annum. This was in the palmiest days of the young Society, when Newton, Boyle, Hooke, Hawkesbee, and many other famous spirits took the most active part in its proceedings, and Papin shared in the work of bringing their experiments, embracing a most miscellaneous range of subjects, before the Society. Amongst the discoveries of his own, of which Dr. Gerland gives a summary, in this way brought before the Royal Society, was the so-called Würtemberg siphon. He also partially anticipated Franklin in his discovery of the ebullition of water under reduced pressure at lowered temperatures, concerning which point he observes: "This shows that liquors being freed from an external pressure will make bubbles upon the score of the elastic particles lurking in their pores, as has been observed long ago by the Hon. Mr. R. Boyle. I do therefore believe that the vapours raised by heat in an exhausted glass will make a pressure, which is quickly taken off when we condense these vapours by putting the glass into cold water or ice." On another occasion Papin brought forward a model of a machine for raising water by pumps to a height, the pumps being worked by a water-wheel driven by the flow of a river. In November, 1687, this occupation came to an end by Papin resigning his post of curator on being appointed by the Landgrave of Hesse to be Professor of Mathematics at Marburg. Here the most active portion of his life began, to be continued when, in 1696, his place of residence was exchanged for Cassel. Here too began the correspondence with Huygens and with Leibniz, which forms the major part of the volume before us. By both of these great men he was highly esteemed. Huygens explained to him in 1690 his new theory of double refraction in a letter of considerable length. Leibniz wrote to Luca about Papin, referring to his ingenious inventions in the most enthusiastic terms. The correspondence with Leibniz went on almost unbroken until Papin's final return to England heart-broken and worn out. That with Huygens ended much earlier, being terminated by Huygens' premature decease in 1695. To Huygens in 1691 Papin writes from Cassel about a project he is undertaking for the Landgrave, to construct a ship on the plan suggested previously by Drebbel to move under water. In the same letter he mentions the production of fog or mist in the receiver of the air-pump, for which phenomenon Huygens, in replying, propounds an explanation. At the same date we find Papin busy with another invention, a *rotilis suctor*, which was nothing else than a centrifugal fan for supplying a blast for furnaces and for ventilating mines, which instrument he had the satisfaction of applying to a mine in Germany in 1699, and six years later he made the further improvements related in the *Philosophical Transactions* of that year. But his greater work was drawing on. In 1698 he writes to Leibniz that he is constructing a machine for raising water to a great height by the force of fire, and that by the success of his experiments he is persuaded that this force can be applied to many other more important ends. Leibniz replied forthwith with the inquiry whether his invention was based upon the principle of rarefaction; adding that he also had some ideas on the point. After two months Papin replies that he relies upon the principle of rarefaction produced by the condensation of steam, but that he proposes also to use the pressure exerted by the steam in expanding, "the power of which is not limited as is that of the suction" (of rarefaction). He also says that he has made a little model of a carriage which is propelled by this force, but that he fears difficulties for such carriages from the inequalities and sharp turns of ordinary high roads—difficulties which for water carriages do not exist. Leibniz's reply is only known

from a summary of it scribbled in his own handwriting upon the back of Papin's letter. He first congratulates Papin on having set himself to this work; expresses his fears lest the direct pressure of expanding steam should produce explosions; and then suggests, "pour faciliter le chariotage," an idea of his own (derived, he says, from the air-pump), that the steam which is to exert pressure should be introduced into a cylinder into which is fitted a second one, after the manner in which our modern gasometers fit into their cylindrical pits, the whole being rendered steam-tight by mercury. Papin, replying in August, announces that his machine has raised water to the height of 70 feet. He only half approves Leibniz's suggestion on account of the probable friction between the internal cylinders. To this Leibniz retorts that while the friction increases with the diameter of the piston of a pump, the pressure increases as the square of the diameter. The matter seems to have dropped at this stage for three years. In 1702 Papin, still at Cassel, announces to Leibniz that he has invented a steam *ballista*, "an invention to facilitate the capture of the strongest places," which "will reduce France to make most promptly a durable peace!" This invention was a cylinder 5 inches in diameter filled with a piston connected to pivoted lever, which on the descent of the piston on the condensing of the steam below it would project a stone weighing 2 lbs. to a distance of 40 feet. (A similar ballista, unknown to Papin, had been suggested by von Guericke, in 1672, in his *Experimenta Nova*.)

Early in January, 1705, Leibniz sent to Papin a sketch of Savery's engine for raising water. This set Papin with renewed vigour to work, besides stimulating to emulation the breast of his patron, the Landgrave of Cassel. After some consideration he pronounced in another letter to Leibniz that he would surpass Savery's invention. He related how he had thought it best not to let the steam act directly against the surface of the water (as in Savery's machine), but that the pressure of the steam should be imparted to the water through the intermediation of a *piston* whose surface, becoming hot, would not produce condensation: and he added that experiment had proved the conjecture to be sound. His great difficulty now was, not to make pistons fit accurately, but to construct tubes sufficiently strong to bear the pressure of such columns of water as he wished to raise. Leibniz congratulated him when replying in August, and advised him not to try to force water high, but rather to lift it by a series of pumps, each drawing 30 feet, a suggestion which Papin on his part rebutted by observing that one force-pump driving water 500 feet high was more economical than ten pumps, each raising the water 50 feet. He further lets Leibniz know that he hopes to do away with the delay of letting the cylinder of his engine cool between each stroke (the very first of the improvements subsequently made by Watt), and that he has some ideas about the transmission of power to a distance, with which problem however he thinks it useless to concern himself, "because by means of the heat-engine one can produce, everywhere where one will, so much power, and so cheaply, that it would be a superfluous expense to carry it elsewhere." Strange commentary, indeed, on the present eager strife of inventors to supersede steam by the electric transmission of power! On October 19 he writes again that he is almost satisfied with his engine, which, though having but one cylinder and two valves, yet furnishes a continuous jet, surpassing Savery's machine, which had two pressure-vessels and four valves: he is only waiting the Landgrave's orders as to how he shall apply his engine to drive a mill. On the last day of the year 1705 he declares to Leibniz his intention of propelling vessels by steam, as he is persuaded that by this means one could have vessels which would follow their course correctly in spite of tempests and adverse winds. At this idea he laboured diligently for the next two years—in fact, so long as he continued to remain at Cassel—his devotion to the object in hand being remitted only for the sake of his correspondence and for the work of publishing his treatise, the "Ars Nova," in which his high-pressure boiler and its applications are described. It was towards the close of this time that (on February 4, 1707) he communicated to Leibniz the first suggestion of a hot-air engine, afterwards realised by Stirling and Ericssen. He was now preparing to leave Cassel, where the patronage of the Landgrave had grown on the one hand slack, on the other irksome, in order to regain the more congenial atmosphere of London and of the Royal Society. He strained every nerve and spent all his little resources to accomplish the building of the steam-propelled boat by which his return to England was to be made famous. He was certain that by this means two men on board his boat might do more than a hundred rowers could. In July and August of that year he made diligent efforts to obtain permission to descend the river *viâ* Münden and Bremen into the Veser, permission which was finally granted by the Elector of Hanover, in spite of the monopoly possessed by the guild of boatmen of Münden to pass boats from the Fulde into the Veser. With a boatman of Münden as captain, he sailed from Cassel on September 24, 1707, with his family. At Münden however the guild of boatmen asserted their privileges, the magistrates pronounced the boat confiscated, and a handsome offer of ransom was rejected. Papin pushed forward despairingly for England; only to find himself almost unknown and friendless. The old generation was fast passing away. For two or three years he continued his mechanical inventions, and several times applied through Sloane for a grant of money from the Royal Society to aid him in his work, but in vain. Misunderstanding and misery followed apace. The inventions on which he relied for fame and position were passed by unnoticed. In the loss of his ship he had made shipwreck of his life's hopes. He died in London, probably, in the early half of the year 1712, but in such obscurity that neither place nor date is with any certainty known.

Dr. Gerland appears to have spared no pains in collecting the scattered facts of Papin's life and work from which to build the volume whose contents we have endeavoured to make known to English readers. We congratulate him on his success, and trust that his efforts will be further rewarded by the discovery of the facts still required to fill the *lacunæ* in the career of this remarkable man. The light which the publication of the correspondence between Leibniz and Papin throws upon the relation between two prominent figures amongst men of science at that time is by no means the least interesting feature of the work; and we must henceforth place

Leibniz amongst the worthies to whom the credit of improvements in the steam-engine is given. The one common feature that runs through the many different types of steam-engine is the piston working within a cylinder. No engine before Papin's time was adapted for any useful purpose except for raising water, and none had a piston in a cylinder. No engine since Papin's time of the thousand varied types has been devoid of this feature. But the very feature which Papin introduced, and on the introduction of which his claim to be called *the* inventor of the steam-engine has been founded, was, as we now know, the suggestion of another mind. We owe the application of the piston-principle in the steam-engine, not to Papin, but to Leibniz.

CHEMISTRY OF THE FARM

The Chemistry of the Farm. By R. Warington, F.C.S. Pp. xiii. and 128. (London: Bradbury, Agnew, and Co., 1881.)

THE chapters of this little handbook appeared originally in detached portions in the *Agricultural Gazette*. They have been revised, and are now issued in a convenient and compact form. A well-ordered manual of agricultural chemistry, clearly written and perfectly abreast of recent advances in the sciences underlying the farming art, has long been wanted. So far as the limits of its size and scope allow, Mr. Warington's volume fulfils our expectations. It is a satisfaction which is seldom afforded us to read a book on agricultural chemistry written by a true chemist trained in laboratory work and versed in the progress made through English and foreign researches. The applications of chemistry to agriculture are manifold, and cannot be grasped by chemists who do not combine with their chemistry a competent knowledge of vegetable and animal physiology and of mineralogy. Yet to learn or to teach the Chemistry of the Farm without a knowledge even of the foundations of chemical science is commonly attempted, though it can never succeed in any true sense. And we quite agree with Mr. Warington that a wider range of scientific knowledge than this is needed even for the student of agricultural chemistry—much more then for the teacher. To talk about this applied science to persons without previous scientific knowledge, and to look for satisfactory results, is to expect a plant unfortunately destitute of roots to blossom and bear fruit.

We think then that Mr. Warington's handbook is valuable on account not only of the knowledge with which its subject is handled, but also on account of the spirit with which that subject is approached. That a new work on agricultural chemistry was sorely needed does not admit of question. In France and in Germany the educational literature of this subject includes many excellent works which have no English counterparts. Johnston's treatise, full as it is of valuable observations, is too thoroughly out of date in method as well as in matter to admit of satisfactory revision; much the same judgment must be passed on Anderson's "Agricultural Chemistry," now twenty years old and out of print. Even if Georges Ville's work on Manures included (which it is far from doing) anything like the whole domain of the Chemistry of the Farm, it is about as unsafe and misleading a book as could be put into the hands of a student. Mr. Warington has given us, in fact, not all we want, but a good bit of it. He has used, and that judiciously, both German and English text-books, researches, and memoirs, and has put the main facts they enounce into a neat form, so as to be "understanded of the people." The two capital text-books of Emil Wolff have been laid under contribution by Mr. Warington; while the chief results of some of the matchless Rothamsted Memoirs by Lawes and Gilbert have been skilfully introduced into his pages. Of the contents of these it is now perhaps time to say a few words. In five chapters the growth, the food, the nutrition, and the products of farm crops are discussed; in another five, animal growth, food, nutrition, and products. Of the diverse origins and properties of soils but little is said; as to the utilisation of urban sewage, nothing. And we should have been glad to have found fuller accounts of many subjects which are but lightly touched upon in these pages. But the difficulty of treating so vast and complex a subject intelligibly in so few pages makes us surprised, not that some things are omitted from, but that such a large number of things are included in, this little book. Some facts and figures which the author would doubtless have liked to introduce have been kept out of his pages by the absolute necessity of finding room for numbers and arguments of primary importance. For instance, it would have been unwise to have curtailed the space bestowed upon the "Digestibility of Foods" and the "Albuminoid Ratio."

In reading through this handbook carefully we have been unable to discover more than a very few statements which we cannot completely endorse; in fact the majority of such alterations as we would suggest would be of form rather than of substance. We cannot, however, refrain from expressing our regret that the percentages of albuminoids in potatoes and roots as given in the table on p. 72 should be the old erroneous figures condemned on the very next page as greatly in excess of the truth. Mr. Warington has however so thoroughly recognised the importance of the discrimination between albuminoid and non-albuminoid nitrogen that we must attribute the inclusion of the incorrect figures in his tables to the difficulty of constructing a complete series of analyses comparable with one another in this particular of the percentage of true albuminoids. A. H. CHURCH

OUR BOOK SHELF

A Handbook of the Vertebrate Fauna of Yorkshire. Being a Catalogue of British Mammals, Birds, Reptiles, Amphibians, and Fishes, showing what species are or have within historical periods been found in the County. By Wm. Eagle Clarke and Wm. Denison Roebuck. (London: Reeve and Co., 1881.)

THIS little volume is dedicated to the President-Elect of the British Association, and most seasonably makes its appearance on the eve of the meeting of that Association in the city and county of its origin, when it will celebrate the completion of the first fifty years of its existence. Its object is the enumeration of those animals with a vertebral column which either are or have been found in Yorkshire, and the careful definition of their faunistic position and geographical distribution within the county. It would appear that there has never been a list of the mammals, birds, or fishes of the county of York published, and in this respect it presents a striking contrast with its neighbouring counties of Norfolk, Northumberland, and

Durham; but by the energetic labours of Messrs. Clarke and Roebuck this reproach no longer exists, and this very useful handbook to the vertebrate fauna of the shire will, let us hope, be soon followed by a second volume, dealing with the larger and perhaps more difficult portion of its, to use a handy term, invertebrate animals. The number of British vertebrata not occurring in Yorkshire being comparatively small, it seemed desirable to the compilers to make this work not only a county handbook, but a complete nominal catalogue of the British species. In this we think they have done well, for such a catalogue undoubtedly furnishes a ready means of comparison with the faunas of other districts. The classification and nomenclature has in all cases been based upon the most recent or the most reliable authorities as to the extinct British mammalia. It having been considered advisable to include notices of these, or at least of such of these as had ceased to exist in Yorkshire within historical times, the species are inserted in their correct zoological sequence, but their names are printed in Old English characters, and they are left un-numbered, as not being now entitled to rank as true members of the fauna. The same has been done in the case of the Great Auk among the birds. To the catalogue is prefixed an interesting chapter on the physical aspect of Yorkshire, the largest county of the British Islands, containing an area of 3,936,242 statute acres—one which, while most compact in form, is perhaps the most varied in geological structure, soil, climate, and physical aspect. The introductory remarks also on the mammals, birds, reptiles, amphibians, and fishes are well worth perusal. From the general summary, the richness of the Yorkshire fauna can be at once seen, it including 513 out of the 717 known British vertebrates. We gladly recommend this volume to our readers, as in every way an excellent and scientific handbook to the vertebrate fauna of Yorkshire.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Schaeberle's Comet

THIS comet, C 1881, was well seen here on the night of Sunday last, the 21st instant. At 9.30, the night being clear, it was at once detected with the naked eye at a point in the north-west, where lines drawn downward through α and β of Ursa Major (the pointers) and γ and δ of the same constellation would intersect, and just above ψ of Ursa Major, a star of the 3rd magnitude. Owing to the comet's close proximity to the horizon I could not use the 6" equatorial, but the position must have been very close upon R.A. 11h. and D.N. 47°. The general appearance to the eye was that of a comet with two nuclei, the one in advance of the other. With a 2½-inch binocular the comet was beautifully sharp and well defined, more so, I thought, than the great southern one when in the same position. The nucleus and star appeared of about the same intensity, but the yellow tint of the latter was strongly contrasted with the almost intense gas blue tint of the former. The tail was well defined, only slightly spreading, and nearly straight, stretching in a line a little to the left of β of Ursa Major, nearly as far as a small triangular group of stars just under β, marked in Maltby's atlas as 44·37 and 246·7. This would give a length of from seven to eight degrees. The tail did not, with the small instrumental power I was using, appear to have any central deficiency of light. The sharpness and brightness of the comet's appearance, as contrasted with the more diffused aspect of the one which has just disappeared, has been remarked upon by several observers.

Guildown, August 22 J. RAND CAPRON

The Descent of Birds

THERE is one passage in the report of Prof. Mivart's lecture on chamæleons (NATURE, vol. xxiv. p. 338) that I cannot allow to pass without demurring to, and that is the suggested probability of a "double origin" for the class Aves. I do not wish at present to raise the issue as to how far the division of all living birds into two groups—"Ratite" and "Carinate"—is, or is not, a natural one; for at present we have not, I think, sufficient information or evidence on the subject to allow of any very definite reply. But any one who is acquainted with the structure of a Tinamu will, I think, be unable to conceive of the many resemblances that group of birds presents to some of the "Ratitæ" as having been developed independently of any genetic connection between the two—and that is what Prof. Mivart's suggestion practically amounts to. That structures so peculiar as feathers—which, as far as we know, are absolutely confined to birds, though universal amongst them—shou'd have been twice over developed, is to me in the highest degree improbable—as improbable, almost, as that the resemblances of the Tunicates and *Amphioxus* to the rest of the Chordata should also be accidental. W. A. FORBES

West Wickham, Kent

Mr. Wallace and the Organs of Speech

IN his article in NATURE, vol. xxiv. p. 244, Mr. Alfred Wallace has given one of the keys to the formation of speech-language. He says, "When we name the *mouth* or *lips* we use labials; for *tooth* and *tongue*, dentals; for the *nose*, and things relating to it, *nasal* sounds; and this peculiarity is remarkably constant in most languages, civilised and savage." Of this he gives examples from Australasia.

Perhaps it may be said there is not much novelty in Mr. Wallace's observations, as many of us have said the same. I have gone over some of his ground in my small "Comparative Philology" in 1852, but I did not hit the point. Indeed what Mr. Wallace gives us is very little, but when it comes to be applied it acquires the highest importance. We have all known that *nose* is often a nasal, but Mr. Wallace distinctly puts it that *mouth* is a labial, *tooth* a dental, and *nose* a nasal. This however gives us by these words and their connections, as stated by Mr. Wallace, a very poor vocabulary, and leaves most of the phenomena of speech-language unaccounted for, and it gives no explanation apparently of the derivation of speech-language from sign- or gesture-language, and the connection of character with both.

Setting Mr. Wallace's illustrations aside—for though they are true, and taken from his own domain, they are not the most apt—we will search farther afield. Chinese will be convenient. In Chinese, for a reason that need not be explained, *mouth* is not now a labial, but in the series connected with it there are many labials. The series is best illustrated by the characters. The old characters are round; the new characters, as in other classes, are now square, conventionally representing the round. Now *mouth* is a round or circle, O (or □). *Ring* is a round or circle O (or □). The character for *mouth* is in fact a *ring*, or round, or circle. On looking for other corresponding characters we have *eye* with O differentiated. Here we get a labial *mu*. *Face* is another round character, and that is *mien*. *Ear*, *head*, *blood*, *pot* (*ming*), *sun*, *moon*, *woman*, *mother* (*mu*), *white* (a labial), *field* or *garden*, *four* are all differentiated forms of each other and of mouth, as we know they ought to be. In cuneiform these characters are round, square, or triangular.

Of many of these psychological relations of words a list or dictionary will be found in the table of equivalents in my "Prehistoric and Protohistoric Comparative Philology." I observed and collected the facts, but did not know the full meaning of them for a long period; and in a paper as yet unpublished by the Biblical Archæological Society I carried the subject still further, particularly as regards cuneiform and Chinese. Indeed, when Mr. Wallace published his article, I had the facts just cited ready for reference in my hand. The reason I did not grasp the solution was this: I have known for years that words forming what I now call ring characters were related to *eye*, and that *eye* is almost a constant in these investigations, equivalent to a molar in various departments of biological research. Indeed it was by the use of *eye* as a constant that I was able to make those numerous and rapid philological analyses which have excited so much distrust among those unacquainted with the process I used.

I found that if I could classify *eye* in a language under examination, it gave me *sun* and many other words, and it led me to much valuable work, but I was often thrown out for reasons I did not then know. Empirically I found *eye* was a constant, and I knew it was a round, because in many languages east and west *sun* is the day eye or day's eye; *moon* is the night eye, and *eye* the head eye. In the North American languages and in the Malay, for instance, there was the evidence of a common law of psychological philology, which led me to greater results. My knowledge became modified to the extent that *sun* was not day eye, but day round. Until Mr. Wallace's article appeared, I still regarded *eye* as the pivot on which the "round" words and characters turned, although I knew that *mouth* was the prototype of *moon*, *mother*, *woman*, *egg*, &c., and of objects and ideas having a periodicity or a month. Having a false pivot, I was never able to bring the facts into a right connection, although coming very near. The Chinese modifications of the ancient character show that *mouth* and *ring* constitute the primary character, and thereby indicate the primary word.

The researches of Col. Garrick Mallery, U.S.A., and my own, in the paper unpublished, show the connection of sign language and characters, and I have determined a relation between sign language, character, and words, as in the sign or character || for son, offspring, &c. The characters in many cases appear as ancient as the signs, and may have preceded speech language. How words were connected with ideas and their representatives by signs was the problem. The new explanations of Mr. Wallace in your paper, or the old observations of others, in giving explanations from natural cries and sounds, &c., are not always exact, and do not account for the fact that the sounds are in relation with the sign language. Thus the words for *eye* and 2 are the same, and the words for *ear* and 3, and so forth.

In the brief remarks now made I endeavour to steer clear of many things which would require a long explanation, and to bring my observations to bear on Mr. Wallace's article. On speech language being constituted, the application of a labial to *mouth* gave a large series, and so of the dentals, &c. As the numerals are in relation to each object of the universe in primitive symbology, so they were supplied. Indeed nouns, adjectives, pronouns, verbs, numerals, particles, were supplied from a common fount. There are languages constituted of a few differentiated words, which can be traced throughout.

In connection with Mr. Wallace's remarks is to be taken what he says afterwards of the action of the lips. In the sign languages and the characters the lower organs supply a large number of ideas regarded as phallic. Such are ||, ·|·, O, &c. These ideas are not capable of direct connection with sounds; they came however into connection by the acknowledged correspondence of the parts in symbology and mythology. Thus the labial sounds became the representatives of actions or ideas illustrated by the corresponding lower organs, as in *go* and *come*.

Taking Mr. Wallace's terms and applying them, we therefore get the connection established between the sign languages and the speech languages, and we can see the psychological grounds on which they continued in working together, and why the speech languages have not everywhere *always* exterminated their ancestors. For this, and for the whole state of affairs, Mr. Wallace furnishes me with an explanation.

His naked statement is the best, that for *mouth* a labial was used. In the sign languages, and we find this in the prehistoric languages and their equivalents, several signs are used for one idea, and several ideas for one sign. When a labial was applied for the *mouth*, it was indifferent what labial. If one used a *b*, another would use *m*. This is one cause of the variety we find in the prehistoric primary languages, for there never was what philologists are fond of, one primitive language.

Many will object to Mr. Wallace, that *mouth* is not always represented by a labial, and in the common course hold that the negative evidence overcomes the affirmative. In many instances *mouth* is a dental, because the idea includes the *teeth*, which are dental. Again *tongue* is not always a dental, but a sibilant, so far as it is connected with *snake*. It is the whole knowledge of the facts which will better enable us to complete our progress and to overcome difficulties. For myself I have derived particular advantage from Mr. Wallace, in being enabled to understand my own work.

HYDE CLARKE

32, St. George's Square, S.W.

Comets and Balloons

THE notion that the tails of comets are produced by an emission of the nucleus prevails at present among astronomers. I have just stated in a small pamphlet, 8vo, 32 pages, the reason why I presume to entertain another opinion on this subject. The details of my last aërial trip of July 2 show that by using an electric light night ascents at a reasonable distance from the sea may be considered as relatively without danger. The appearance of Schäberle's comet seems to me to afford a proper occasion for testing the emission theory, and I will try to explain my idea as shortly as possible.

It is pretty certain that any comet will lose something of its brilliancy in consequence of passage to the perihelion, consequently, *cæteris paribus*, it must be found with a diminished luminous power in the second part of its track. The consequence is that to test this theory the same comet should be observed in a similar position, as close as possible, in the first and in the second parts of its track.

By ascending with a balloon in the northern hemisphere to inspect Schäberle's comet on a moonless night, and estimating its luminous power in a clear sky at several determined heights, a great step will be made in reaching this desirable end.

It would be for the astronomers of the southern half of the world to ascend under similar conditions, and to make corresponding observations. If no visible diminution is proved to have taken place, much will have been accomplished in the determination of the true nature of this mysterious object.

The same observations could, it is true, be prosecuted without the help of aërostation, but not with the same amount of certainty, as much doubt remains as to the true luminosity of a celestial body when it is not inspected in a really perfectly clear sky, which can always be procured with a balloon—it is true not without incurring some personal risk, certainly not out of proportion, at all events, to the results to be expected.

W. DE FONVIELLE

Animal Instinct

I AM exposed to some annoyance from a clever old donkey, who, being turned out on to the green in front of my house, constantly lets himself into my garden to graze on my lawn. This he effects by pushing his nose between the rails of an iron gate, and then pressing down the latch of the gate. Expulsion, with ever so striking an appeal to his feelings, avails only a short time for his exclusion, unless the gate is locked.

Little Park, Enfield, August 19 W. B. KESTEVEN

ITALIAN DEEP-SEA EXPLORATION IN THE MEDITERRANEAN

AFTER my communication of the 4th inst. from Asinara I feel sure that many readers of NATURE will be interested to know something more of our doings; so I take the opportunity of our short stay here to send a very brief account of our doings since leaving Asinara.

The presence of a deep-sea fauna in the Mediterranean which I announced in my last is fully confirmed, and even though most of the species dredged are as yet undetermined, I can venture to say that the character of this fauna is "Atlantic," and, I may add, "Oceanic." My first bit of news was the capture of a *Willemœsia* identical, or very nearly allied, to *W. leptodactyla;* since then some ten or twelve specimens of that most interesting and characteristic Crustacean have been secured off the west, south, and east coasts of Sardinia, in depths varying from 950 to 2145 metres. All our deep hauls have brought up some living animals, usually Annelids and deep-red shrimps of at least three species; the greatest depth we have trawled in is 3115 metres; the greatest we have found sounding is 3630 metres in the eastern basin between Sardinia and Naples.

On the 10th inst., off the west coast of Sardinia we dredged two specimens of a Macrurid fish, which I take to be a *Malacocephalus*, from depths of 2805 and 2908 metres. South of the Gulf of Cagliari we got a new—to me—and exceedingly remarkable Macrurid, with what

look like the so-called supplementary eyes along the belly and tail, the rare *Macrurus sclerorhyncus*, *Hoplostethus Mediterraneus*, and *Haloporphyrus lepidion*, from depths of 508, 656, 860, and 1125 metres. We have at least two species of *Terebratula* from depths varying from 600 to 1200 metres. Several most interesting Crustaceans besides those mentioned, and even a non-swimming Brachyurous Decapod, from 1125 metres! But what is still more interesting is the capture of several specimens of a *Hyalonema*, very probably *H. Lusitanica*, but without any spiral twist in its long spiculæ; we got them off the south and east coasts of Sardinia, in depths from 1600 to 623 metres; we have, besides, several other forms of Sponges, all siliceous, and several of a curious agaric-like form. We have a *Brisinga* from depths of 2145 to 2300 metres, but very few other Echinoderms; I do not yet give up the hope of seeing a *Pentacrinus* before our cruise is ended. We have, as I mentioned, various Annelids and Gephyreans, and some fine species of Madreporia of the deep-sea forms.

We have an interesting set of serial thermometric observations, which show that there is a slight difference in the bottom temperature between the basins east and west of Sardinia, the latter being slightly colder. Negretti and Zambra's new deep-sea thermometers have answered admirably, suspended in the peculiar frame devised by Capt. Magnaghi. HENRY HILLYER GIGLIOLI

Naples, August 20

ON THE VELOCITY OF LIGHT

THE result announced by Young and Forbes (Roy. Soc. *Proc.*, May 17, 1881) that blue light travels *in vacuo* about 1·8 per cent. faster than red light, raises an interesting question as to what it is that is really determined by observations of this character. If the crest of an ordinary water wave were observed to travel at the rate of a foot per second, we should feel no hesitation in asserting that this was the velocity of the wave; and I suppose that in the ordinary language of undulationists the velocity of light means in the same way the velocity with which an individual wave travels. It is evident however that in the case of light, or even of sound, we have no means of identifying a particular wave so as to determine its rate of progress. What we really do in most cases is to impress some peculiarity, it may be of intensity, or of wave-length, or of polarisation, upon a part of an otherwise continuous train of waves, and determine the velocity at which this *peculiarity* travels. Thus in the experiments of Fizeau and Cornu, as well as in those of Young and Forbes, the light is rendered intermittent by the action of a toothed wheel; and the result is the velocity of the group of waves, and not necessarily the velocity of an individual wave. In a paper on Progressive Waves (*Proc.* Math. Soc. vol. ix.), reprinted as an appendix to vol. ii. of my book on the "Theory of Sound," I have investigated the general relation between the group-velocity U and the wave-velocity V. It appears that if k be inversely proportional to the wave-length,

$$U = \frac{d(kV)}{dk},$$

and is identical with V only when V is independent of k, as has hitherto been supposed to be the case for light in vacuum. If however, as Young and Forbes believe, V varies with k, then U and V are different. The truth is however that these experiments tell us nothing in the first instance about the value of V. They relate to U; and if V is to be deduced from them it must be by the aid of the above-given relation.

When we come to examine more closely the form of this relation, we see that a complete knowledge of V (as a function k) leads to a complete knowledge of U, but that a complete knowledge of U—all that experiments of this kind can ever give us—does not determine V, without the aid of some auxiliary assumption. The usual assumption is that V is independent of k, in which case U is also independent of k. If we have reason to conclude from observation that U is not independent of k, this assumption is disproved; but we can make no progress in determining V until we have introduced some other.

It is not easy to see how the missing link is to be supplied; but in order to have an idea of the probable magnitude of the difference in question I have assumed the ordinary dispersion formula $V = A + Bk^2$ to be applicable. Taking the ratio of wave-lengths of the orange-red and green-blue lights employed as 6 : 5, I find that for red light $V = U(1 - \cdot0273)$, so that the velocity of the wave would be nearly 3 per cent. less than that given by Young and Forbes as the result of the experiment.

Under these circumstances it becomes a matter of interest to examine the bearing of other evidence on the question of the velocity of light. Independently of the method of the toothed wheel, the velocity of light has been determined by Foucault and Michelson using the revolving mirror. It is not very obvious at first sight whether the value thus arrived at is the group-velocity or the wave-velocity, but on examination it will be found o be the former. The successive wave-fronts of the light after the first reflection are not parallel, with the consequence that (unless V be constant) an individual wave-front rotates in the air between the two reflections.

The evidence of the terrestrial methods relating exclusively to U, we turn to consider the astronomical methods. Of these there are two, depending respectively upon aberration and upon the eclipses of Jupiter's satellites. The latter evidently gives U. The former does not depend upon observing the propagation of a peculiarity impressed upon a train of waves, and therefore has no relation to U. If we accept the usual theory of aberration as satisfactory, the result of a comparison between the coefficient found by observation and the solar parallax is V —the wave-velocity.

The question now arises whether the velocity found from aberration agrees with the results of the other methods. A comparison of the two astronomical determinations should give the ratio $U : V$, independently of the solar parallax. The following data are taken from Mr. Gill's "Determination of the Solar Parallax from observations of Mars made at the Island of Ascension in 1877."

The time k, required by light to travel a mean radius of the earth's orbit, has been determined by two astronomers from the eclipses of Jupiter's satellites. Delambre found, from observations made in the last century, $k = 493{\cdot}2$s., but recently Glasenapp has obtained from modern observations the considerably higher value, $k = 500{\cdot}8$s. $\pm$ 1·02. With regard to the constant of aberration, Bradley's value is 20″·25, and Struve's value is 20″·445. Mr. Gill calculates as the mean of the best modern determinations (nine in number), 20″·496.

If we combine Glasenapp's value of k with Michelson's value of the velocity of light, we get for the solar parallax 8″·76. Struve's constant of aberration in conjunction with the same value of the velocity of light gives 8″·81. From these statements it follows that if we regard the solar parallax as known, we get almost the same velocity of light from the eclipses of Jupiter's satellites as from aberration, although the first result relates to the group velocity, and the second to the wave velocity. If instead of Struve's value of the constant of aberration we take the mean above spoken of, we get for the solar parallax 8″·78, allowing still less room for a difference between U and V.

Again, we may obtain a comparison without the aid of the eclipses of Jupiter's satellites by introducing, as otherwise known, the value of the solar parallax. Mr. Gill's

value from observations of Mars is 8″·78, agreeing exactly with Michelson's light velocity and the mean constant of aberration. Some other astronomers favour a higher value of the solar parallax, such as 8″·86; but whichever value we adopt, and whether we prefer Cornu's or Michelson's determination of the light velocity, the conclusion is that there can be no such difference between the group velocity and the wave velocity as 2 or 3 per cent., unless indeed the usual theory of aberration requires serious modification. These considerations appear to me to increase the already serious difficulties, which cause hesitation in accepting the views of Young and Forbes. The advent of further evidence will doubtless be watched with great interest by scientific men.

One other point I may refer to in conclusion. Speculations as to harmonic relations between various spectral rays emitted by a glowing gas proceed upon the assumption that the frequency of vibration is inversely proportional to the wave-length, or, in other words, that the velocity of propagation V is independent of the wave-length, the question now at issue. If the views of Young and Forbes are correct, calculations of this kind must be overhauled. On the other hand, the establishment of well-defined simple ratios between wave-lengths would tend to show that V does not vary. RAYLEIGH

August 15

ELECTRIC LIGHT IN COLLIERIES

AUGUST 9, 1881, witnessed the first practical application in the United Kingdom of the electric light to the illuminating of coal-mines. The Earnock Colliery, near Hamilton, Lanarkshire, belonging to Mr. J. Watson, has been fitted with Swan's incandescent lamps specially arranged with outer lanterns of stout glass, air-tight, and provided with steel guards. The workings in which the lamps were fixed are 118 fathoms, or 708 feet below the surface. Twenty-one brilliant little lights placed at the pit-bottom, in the roads, and at the actual face of the seam where active operations were in process, supply an illumination of a very different character from the dismal glimmer of an occasional Davy. The electricity was generated by a dynamo-electric machine at the surface worked by a special 12 horse-power engine, and conveyed by two cables, first along telegraph poles to the pit mouth, then down the shaft to the workings, in one section to a distance of half a mile. The overhead wires are naked copper wires of $\frac{3}{8}$ inch diameter, while those below ground are carefully insulated, and in the shaft are protected with an outer tube of galvanised iron. At suitable points of the circuit safety air-tight switches, the invention of Messrs. Graham of Glasgow, are inserted to afford control over individual lamps. The mine was visited two days after the installation of the light by members of the Mining Institute of Scotland, with whom was Mr. W. Galloway, whose remarkable experiments on the explosive effects of coal-dust will be remembered in connection with the more recent report of Prof. Abel. The party were photographed in the workings. An experiment was made with a lamp to test whether in the event of its being broken by accident a surrounding atmosphere of explosive gas would or would not be kindled by the strip of red-hot carbon before it had had time to cool. Into a box containing about three cubic feet of explosive gas a single lamp, removed from its outer protecting case of stout glass, was placed, and the current was turned on. The fragile bulb inclosing the incandescent carbon thread was then purposely broken, when the gas inclosed in the box immediately exploded. No such occurrence could possibly happen if the protecting case of stout glass is properly constructed. The risk of accident must be considered as immensely less than that of the ordinary Davy lamp, especially when it is remembered that with the brilliant light of the electric lamps they need no longer be carried in the hand or set down upon the floor near the actual spot where the coal is being got, but will be fixed overhead at a safe distance against the wall of the mine. The ease with which the light can be turned out during the firing of a blast is another point in their favour. The proprietor of the Earnock Colliery is greatly to be congratulated on the step he has taken. In 1880 the death-roll of the slain by explosions of fire-damp in Great Britain reached the figure of 499 persons. We venture to predict that the universal adoption of electric lighting in fiery mines would reduce this figure to one-tenth of its terrible proportions. How many years will it be, we wonder, before the adoption of electric lighting will be made compulsory by Act of Parliament? And how many colliery owners will discover, we would ask, when driven to this course by compulsion, that in the long run they effect an economy by discarding the clumsy and unsafe "safety"-lamp, which will so soon be numbered with the "flint mill" amongst the relics of the past?

SINGULAR STONE HATCHETS[1]

MONSIEUR PITRE DE LISLE has lately called attention to a singular class of stone celts or hatchets which have for the most part, if not indeed only, been found in Brittany and North-Western France.

These hatchets, instead of tapering away to a more or less conical point at what has been termed the butt-end, suddenly expand close at that part, so as to present a somewhat button-like termination. In one instance, at least, the hatchet ends in a spheroidal ball not unlike that which one occasionally sees on the horns of cows which are inclined to make too free use of their natural arms of offence. In the case of the hatchets, however, the button is at the opposite end to that which was in use for cutting. These blades vary in length from about three inches to as much as fifteen inches, and are all made of rocks belonging to the family of Diorites, principally of Aphanite.

M. de Lisle has given to these instruments the name of "*haches à tête*" or "*haches à bouton*," and has pointed out the similarity which in some respects they bear to hatchets of Carib origin and to the *merés* of New Zealand. In these instances the object in view in fo[illegible]g a projecting rib round the end of the blade was no doubt to afford the means of preventing it from slipping out of the handle or hand which held it. He thinks that the same object led the makers of these French blades to adopt the same form, and that the hatchets, after passing through a transverse hole in their hafts, were secured by cords wound around them, which abutted against the projecting rims at their small end. In his opinion there is a representation of this method of hafting to be seen among the sculptures on the dolmen of Mané-Lud.

It is a remarkable circumstance that the hatchets of this particular form appear to be restricted to so small a district of France, and not to occur elsewhere. M. de Lisle is in consequence inclined to assign the development of this type to a late period in the Neolithic age, and has offered some reasons for inferring that in Brittany the use of bronze hardly found a home, and that stone was the principal material employed for cutting tools when first that part of Gaul was brought in contact with Roman civilisation. It seems probable enough that in that as in other countries there were districts which lay far away from the principal highways of progress and civilisation, and where old-world usages prevailed long after material advances had been made in more fortunate but not very distant regions.

We may however be allowed to doubt whether the country of the Veneti, the most enterprising maritime tribe of Gaul, whose ships in the days of Julius Cæsar were already provided with chain-cables of iron, were

[1] "Les Haches à Tête de la Pretagne, etc." (Nantes, 1880.)

among those in the rear of civilisation. However this may be, M. Pitre de Lisle has done good service to archæology in publishing his monograph upon this peculiar form of stone implement or weapon.

INTERNATIONAL BUREAU OF WEIGHTS AND MEASURES

UNDER the authority of the Comité International, representing several countries of Europe, the United States, and South America, there has been recently published, by Gauthier-Villars of Paris, an important volume of Memoirs by Dr. Broch (Directeur du Bureau), and Drs. Pernet, René-Benoît, and Marek (Adjoints du Bureau), on the following subjects relating to the determination of units of measure and weight.

As the intensity of weight varies with geographical position and height above level of the sea, the Comité give in their first memoir tables of the ratio of the acceleration of weight at the level of the sea, for different latitudes, to its acceleration at latitude 45° (Paris), to which latitude the Comité recommend that all weighings might be referred. The tables are based on the formula of Laplace, the coefficients of which are corrected by Broch in accordance with recent deductions as to the figure of the earth. In the second memoir, which relates to the tension of aqueous vapour, certain corrections of hitherto accepted results are also indicated, particularly the errors of calculation in Regnault's tables as shown by Moritz, and new tables are given for tensions at all absolute barometer heights for normal degrees from − 30° to + 101° C.

With reference to the fixed points of mercurial thermometers, the Comité adopted the proposition that the point 0° of the Centigrade thermometer should be fixed at the pressure of 760 mm., when determined in 45° latitude, and at the mean level of the sea. Also at the Congress of Meteorologists at Rome in 1879 there was adopted the proposition of Dr. Pernet, to fix the boiling point of water, 100° C., under the above pressure, so as to render strictly comparable the temperatures observed at different places. Degrees of temperature between these points are termed normal-degrees.

Tables are also given, by which may be calculated the weight of a litre of pure air in different latitudes and at different altitudes. In London (lat. = 51° 30′, alt. = 67 metres) the weight is 1·2938 grammes. The Comité have adopted the term litre for expressing the volume of a kilogram of pure water, instead of the term cubic-decimetre.

In a report by M. Herr on the Austrian unit of weight (Vienna, 1870), the volume of pure water at various temperatures is stated from the means of observations by Muncke, Stampfer, Kopp, and Pierre, the maximum density of water being taken at 3°·92796 C. By this formula there have been calculated, under the directions of the Comité, tables of the volume and specific weight of water from 0° to 30° C.

One of the principal works executed during 1878-9 was the comparisons of the standard kilograms at Vienna, Paris, and London. An elaborate report on these comparisons is given by M. Marek, who, by improved methods and instruments, has obtained great accuracy. The probable error of his weighings is about 0·002 mgr., or 1-500,000,000th part of the whole weight. The results also show that the material of which the standards are made, 90 per cent. of platinum and 10 per cent. of iridium, is of all known bodies the least affected by time or atmospheric changes.

In a paper on Fizeau's apparatus for determining the rates of expansions of bodies by heat, by means of an optical method founded on the phenomena of interference, Dr. Benoit gives the results of his own experiences with a similar apparatus. The results show the wonderful delicacy of Fizeau's dilatometer, as the expansions by heat of small specimens of platinum are shown in a manner incontestable to millionths of a millimetre (0·00000004 inch).

An interesting account of the establishment and objects of the Bureau is given in a preface to this volume by the Secretary to the Comité, Dr. Ad. Hirsch; and it is hoped that the efforts made by the Comité to bring about international agreement on the scientific points above referred to will commend themselves to all engaged in accurate work.

H. J. CHANEY

A MODEL PUBLIC LIBRARY

ENGLISHMEN are fond of descanting upon the evils of too much centralisation, which they see displayed in some foreign systems of government, urging the amount of red tape rendered almost necessary, its inflexibility, and lack of adaptation to the infinitely-varying circumstances of different communities. But, on the other hand, the extravagant cost of working every undertaking by a separate organisation, especially in a community not large enough to make such undertakings great matters, must come forcibly home to many of those who are naturally selected to work upon several.

There has lately come under our notice an admirable case of a public library avoiding this waste, securing all the energy of private zeal, and at the same time increasing the working power of it by becoming, as a public library should become, the centre of all secondary education and the parent stem of many and various branches. If any of the smaller towns of England feel that a free library would not in their case stand by itself on account of small income, we commend this to their notice as a specimen of the advantages of co-operation.

Watford has a population of about 10,000, and the penny rate on last year's gross rental of 34,589*l.* brought in 144*l.* 2*s.* Yet this small amount has developed round it an expenditure of 700*l.* a year, equal to five times the largest rate collected, besides a large outlay on buildings at the beginning, costing some 3000*l.* subscribed, in addition to the gift of the land. Ten distinct sections are worked in connection with it. The accounts of each are shown in a separate balance-sheet each year, and the agenda paper, with notice of committee-meetings, shows how methodically the work of each section is carried out and overhauled.

Section A, the Library proper, contains about 7000 volumes; a payment of three shillings a year, or fourpence a month, is required for taking books home to read; the yearly issues accordingly amount to about 12,000. The only *free* part of the library, the reading-room, shows a something similar use of books; it is patronised chiefly by young men in the winter time, under the arrangements of Section D. The small subscription enables the book committee to spend about 50*l.* a year in new books; magazines and periodicals being supplied by a separate club, connected, of course, with the institution. We should be glad to see the troublesome and irksome system of guarantors dropped. Towns which have freed themselves from the labour and annoyance they entail, though containing far larger proportions of the "great unknown" than can a place of the size of Watford, have found no evil result. The subscription also, though small, seems to render it less necessary here.

Section B is the School of Science and Art, the latter division showing clearly that the public library at Watford by no means attends to the wants of the industrial classes only, for non-Government pupils may pay six guineas a year for drawing only. For the benefit of the evening classes, at which non-Government pupils pay a guinea and a half for the year's instruction, and Government students (whose income, that is, or parents' income, does not exceed 200*l.* a year) half that, "the subjects are

arranged to meet the requirements of artisans and those engaged in mechanical trades, and include mechanical drawing, building, construction, modelling, model drawing, outline drawing, and shading."

This section includes science teaching also, and classes were formed last year in inorganic chemistry, botany, principles of agriculture, fully illustrated by experiments; shorthand also, a useful help to all such studies.

Section C is Entertainments, and is set going or stopped as occasion offers; of course it is expected to be a help to the general fund.

Section D is the Youths' Institute, supported also by special honorary subscribers and by one penny a week paid by its members for admission to the reading-room, *because without that the room was too full*. Let us hope that such a very unsatisfactory statute of limitations may soon cease to be necessary. An extra rate would hardly be grudged in such a case, and it is a strong argument for Parliament authorising one.

Section E is a Private Subscription-room, supported by about a hundred members, who subscribe ten shillings a year each, spent in newspapers and periodicals, made available to the public after their use by the club.

Section F is a School of Music, where some of the best masters obtainable in London are engaged, two of whom take the combined instruction, and four take separate instruction. Nine different classes of lessons are arranged for, again not free, but all made available to those who wish for them, at very little expense or labour to themselves. It is now supported by 160 students, and by subscriptions from the vice-presidents.

Section G is the nucleus of a Museum; and how treasures of local interest are lost to a town for want of such a nucleus in trustworthy hands, the writer knows well! Central museums also can easily supply duplicate treasures to such institutions in almost perpetual succession.

Section H, the English Literature Club, meets weekly through the winter, at the library rooms, adding greatly to the care with which books are read, and, consequently, to the pleasure and information drawn from them. A very small subscription pays its, no doubt very small, expenses.

Even needlework in elementary schools, though spread about half the County of Herts, and patronised by a goodly company of influential ladies throughout the district, has its "head centre" in a committee of three gentlemen of the Watford Public Library. Fifty-four schools compete, and 1500 specimens are shown, in six classes of work, all having undergone a strict and very systematic examination.

The same association supports also a School of Cookery.

Other offshoots of the Library are the Herts Natural History Society, the Foresters' Club, Junior Foresters' Club, and the Shepherds' Club, each having its meeting-place at the library rooms.

Now among this variety of work there is probably none which is not carried on in nearly all the larger towns of England by *some* means. What we wish to set forth is the reasonableness of its all forming together the work of a single "committee of education," not necessarily elementary only by any means; and that a rate-supported public library should be the central institution, whose committee should set in co-ordinate motion all the parts of this local educational machine. Such a committee need not attempt to take into its hands the entire control of each separate branch, but should work all together with as little friction and loss of labour as possible, and especially should this be the case, as we have said, in our smaller towns. Very great is the economy of one institution working all together, in the matter of rooms, advertising, and printing; in one man receiving, as the librarian does at Watford, all the subscriptions and fees paid to these various societies, the 5 per cent. allowed him upon all giving him a tangible interest in increasing each, as such a central worker must have the means of doing, and in stirring all up to a friendly rivalry in well-doing. And the advantage can hardly be over-stated of the power of such an organisation to bring together earnest workers, who might otherwise have followed either a secluded path or one crossing that of other workers; in the one case, occurring most frequently in small communities, doing little for the advance of intelligence and information; and in the other case, to which large cities are most liable, wasting time and efforts which are often thwarted by mere local jealousies.

NOTES

In June of the present year the freshwater jelly-fish (*Limnocodium Sowerbii*) reappeared in the Royal Botanical Society's Gardens, Regent's Park, though in no great numbers. At the suggestion of Mr. George Busk, F.R.S., and with the courteous assistance of Mr. W. Sowerby, a small number were captured and transferred to the Victoria tank in Number 10 House at the Royal Gardens, Kew. Nothing was known of their fate till about a week ago, when it was observed that the whole tank was swarming with the progeny of the small colony brought from London.

The Local Committee at York have been making laudable exertions for the accommodation of those who intend to be present at the meeting of the British Association next week. They have prepared a long list of hotels and lodgings, with prices, at the same time stating that the prices of the lodgings are higher than will be eventually charged, "as there is abundance of good accommodation at reasonable rates." They have also issued a time-table of the arrivals and departures of trains at York station from the principal towns in the kingdom, with special tables for the local lines. A map of the city has besides been prepared, showing the situation of the principal buildings, the meeting-places of the various sections, and the principal hotels, of which there are fourteen.

The *Times* Geneva correspondent gives some further particulars concerning Prof. Raoul Pictet's model steamer now in course of construction, with which he expects to reach a speed of forty miles an hour, and which will make a trial trip on the lake in November next. Her dimensions are—16 metres long and 3·50 metres wide. When lying at anchor she will draw 33 centimetres fore and 44 centimetres aft; at full speed 1 centimetre forward and 16 centimetres aft. The engine will be placed amidships, from which point to the stern the screw-shaft and the keel form an inclined plane; the bows are long, tapering, and wedge-shaped. Prof. Pictet reckons that his invention will lead to a great saving of fuel, inasmuch as a steamer built on his plan, after being started with say 100 horse-power, may be kept up full speed with an expenditure of force equal to thirty horses. The form of the hull, on which the maintenance of the ship's equilibrium will depend, cannot be explained without a diagram. Prof. Pictet is quite confident in the success of his invention, and his previous scientific achievements have been so remarkable that many people who cannot follow his reasoning have no hesitation in accepting his conclusions.

The inhabitants of Havre are collecting money for raising a statue to Sauvage, who is considered in France as having applied the screw to the propelling of steamers.

A telegraphic experiment of a singular description was tried last week at the Trocadéro. It consists merely in the reading of large silvered zinc letters, a square metre in size, fixed on a blackened board, by refracting telescopes. This method has succeeded very well from the Trocadéro to the Panthéon, a distance of about three miles. The inventor, an

officer in the French service, thinks he will succeed in reading messages at a distance of sixty miles under favourable circumstances.

M. EUGÈNE GODARD, the celebrated French aëronaut, who has been making ascents at Gotha, has been made by the Grand Duke a knight of his order. M. Darmentiers, another French aëronaut, having ascended from Montpelier, has been less successful. He was driven by a strong wind out to the Mediterranean Sea, where he perished according to all probability, no news having been received from him up to the latest date.

AN advertising vehicle is circulating in the Paris streets lighted at night by voltaic electricity obtained by bichromate elements. It circulates all round the Boulevards.

THE triple granite concentric vaulting of the St. Gothard Tunnel, in the quicksand formation under Andermatt, is now completed, and as the rings previously constructed remain intact, it is confidently hoped that a difficulty at one time thought to be insuperable has been conquered, and that the great tunnel will be finished by the end of October.

FROM the Report in the last Technological Examination of the City and Guilds of London Institute we see that the number of candidates and centres for examination have largely increased. The results are generally better than in the previous year, though from the examiner's reports there is, in most subjects, much to be desired. No doubt in the course of a few years, when the Institute has been fairly at work, the improvement in technical knowledge in the country will be very marked.

AN official investigation shows that the phylloxera infests an area of over 8000 square metres of the vineyards at Heimersheim, near Remagen, on the Rhine. The diseased vines were imported from Austria. Energetic steps are being taken for the annihilation of the disease.

THE death is announced of Capt. Popelin, one of the Belgian African explorers, who had established the station at Karema, on the south-east shore of Lake Tanganyika, where, apparently, he has succumbed to fever. Capt. Popelin was only thirty-four years of age.

THE British Archæological Association is holding its meetings at Malvern, which forms an admirable centre for excursions to antiquities of all kinds.

THE "Polytechnic" expires this week, many of our readers will be sorry to hear. The age seems to have outgrown its toy science, though doubtless the institution did good in its day in paving the way for the popularisation of real science. In the memories of our older readers it will doubtless be associated with many a happy day.

MR. WILLIAM ARCHER, F.R.S., Librarian of the National Library of Ireland, has just issued a pamphlet which we commend to his fellow-librarians. The pamphlet consists of "suggestions as to public library buildings, their internal plan and construction, best adapted to effect economy of space (and, hence, saving of cost), and at same time most conducive to public, as well as administrative, convenience, with more especial reference to the National Library of Ireland." We cannot enter into the details discussed by Mr. Archer, but his leading principles as to arrangement may be thus summed up in his own words:—"Central reading-rooms and offices connected, by short and sufficiently numerous radii, with a continuous circuit of book-rooms around and beneath the same, the books in the book-rooms on a greater or less number of tiers of standing presses, these not more than eight feet high—thus securing the immense boon of the abolition of ladders and galleries, and saving at once space (and cost) as well as the time of the public." Mr. Archer draws attention to the fact that the question of space is gradually becoming more and more urgent as regards this, the only large public library in Ireland, and that if the providing of enlarged accommodation is to be delayed until a science and art museum and a metropolitan school of art should be built, so as to hand over the buildings at present occupied by these for library purposes, it looks very probable that the library must come to a "stand still." He states further that the number of readers was never before so great as during the past winter, the evening readers having especially increased. The National Library of Ireland, therefore, even in its present cramped and inadequate quarters, is fulfilling a mission of usefulness.

AN important discovery has been made in the vicinity of Kenneh, Upper Egypt. No less than thirty-six well-preserved sarcophagi have been brought to light. They almost exclusively belong to the kings and queens of the older Thebes Dynasty. They contained mummies, papyrus scrolls, Osiris statuettes (some thousands), ornaments, and talismans. The royal names of Raskenes, Amenophis I., Ahmes, Nofretari, Aahhotep, Totmes II. and III., Seti I., Ramses XII., Pinotem, and other Pharaohs are mentioned in the texts, and show the importance of the discovery. The sarcophagi were all found in one sepulchral chamber.

THE "Smithsonian Report" for 1879 affords ample evidence that the Smithsonian Institute continues to carry on its great work with increasing efficiency. Its grants of money have been devoted to the carrying out of anthropological researches and geographical explorations, and to the publication of a large number of works bearing on the progress of science. Large additions have been made to the various departments of the free museum of the Institute. The Appendix to the Report, occupying the larger half of the volume, contains a number of papers bearing on the anthropology of the North American Indians, one paper of considerable length being "A Study of the Savage Weapons at the Philadelphia Exhibition," by Mr. E. H. Knight. Other papers in the Appendix are: "On the Present Fundamental Principles of Physics," by Prof. Franz Joseph Pesko; "A Universal Meteorograph, designed for Detached Observatories," by Prof. E. S. Holden.

THE *Transactions* of the Norfolk and Norwich Naturalists Society for 1880–81 contains several useful papers. One of the most interesting is that of Mr. Southwell, "On the Extinction of Species by the Indirect Acts of Man." Mr. Southwell adduces a number of instances in point, showing that experimental acclimatisation sometimes leads to disastrous results. Mr. H. W. Feilden contributes some remarks on the Natural History of Franz-Josef Land. From the presidential address we are glad to see that the Society continues to prosper.

A SHORT time ago a colossal whale was captured and killed on a sandbank near Westerland-Lylt (Schleswig). It measured 52 feet in length, 26 feet in circumference, and its tail-fin spanned 7 feet across. The animal must have entered the Watten Sea during high tide and lost itself in shallow water, when the receding tide left it upon the sand.

THE Medical and Sanitary Exhibition, organised by the Committee of the Parkes Museum, was open for the last time on Saturday, August 13, when the number of visitors, exclusive of season-ticket holders, was 1,221, making a total of 24,333 visitors for the four weeks during which the Exhibition has been open, allowing only for one visit by each season-ticket holder. During the day the secretary, Mr. Mark Judge, visited the different exhibitors for the purpose of ascertaining their opinion as to the success of the Exhibition. The exhibitors generally expressed themselves as well satisfied with the result, some going so far as to say that they had done an exceptional amount of business owing to the fact that a very large proportion of the

visitors had been either medical men, architects, or engineers. The representatives of the exhibitors, who have been in daily attendance during the Exhibition, marked their appreciation of the arrangements made for their convenience by presenting on Saturday a small purse of gold to the superintendent, Mr. Smithson. The closing of the Exhibition was taken advantage of by the St. John Ambulance Association to give a demonstration of ambulance practice, and during the afternoon a large number of the visitors assembled in the conservatory to witness the practice, which was conducted by Major Duncan, Mr. Cantlie of Charing Cross Hospital, Mr. Furley, Dr. Crookshank, and Surgeon-major Baker. Prizes were competed for by squads of the Grenadier Guards, the Finsbury Rifles, and the Metropolitan Police. Mr. John Eric Erichsen (the chairman), Dr. Poore, Dr. Steele, Mr. George Godwin, Mr. Rogers Field, and other members of the Exhibition Committee were present during the day. It is expected that the prizes which have been awarded will be distributed at the Annual Meeting of the Parkes Museum in the autumn.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Mr. E. O. Brookfield; a White-collared Mangabey (*Cercocebus collaris*) from West Africa, presented by Mr. James Jameson; a Diana Monkey (*Cercopithecus diana*) from West Africa, presented by Mr. Louis Wyatt; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. R. Edge; two Vulpine Phalangers (*Phalangista vulpina*) from Australia, presented by Mr. George White; a Lesser Sulphur-crested Cockatoo (*Cacatua sulphurea*) from the Moluccas, presented by Mrs. Beard; two Wonga-wonga Pigeons (*Leucosarcia picata*) from New South Wales, presented by Mr. J. Burnham; a Royal Python (*Python regius*) from West Africa, presented by Mr. G. H. Garrett; a Grey Parrot (*Psittacus erithacus*) from West Africa, deposited; a Lesser White-nosed Monkey (*Cercopithecus petaurista*), two Pluto Monkeys (*Cercopithecus pluto*) from West Africa, purchased; a Zebu (*Bos indicus*), a Pampas Deer (*Cariacus campestris*), born in the Gardens. Amongst the additions to the Insectarium during the past week are pupæ of *Attacus aurota* (one of which has since emerged) and *Ceratocampa ixion*, from Brazil; larvæ of the Madder Hawk-Moth (*Deilephila gatii*), the Death's-head Hawk-Moth (*Acherontia atropos*), the Poplar Hawk-Moth (*Smerinthus populi*), and Fox Moth (*Bombyx rubi*), and perfect insects of the Water Stick-insect (*Ranatra linearis*).

PHYSICAL NOTES

M. SAMUEL, of Ghent, has brought before the Belgium Academy a method of registering telegraphic signals received through the mirror galvanometer (*Bull.*, No. 5). On the screen receiving the light are fixed two selenium elements, one to the right, the other to the left. When either is illuminated its conductivity of course increases, and it acts as a relay on an electro-magnet, which causes a Morse dot or dash to be marked on paper. There are two local batteries, one having two circuits, which pass through the selenium pieces and the electro-magnets, while the other is for the electro-chemical writing. In this latter, a band of paper saturated with iodide of potassium passes continuously over a small copper cylinder which is connected with one pole of the second battery. Above the paper are the ends of the armatures of the electro-magnets; to one is attached a vertical platinum rod, to the other a small triangle with platinum base (horizontal). The rod and triangle are connected, through the armatures, with the other pole of the second battery, and they press the paper band on the cylinder each time the armatures are attracted, giving a dot or a dash as the case may be. The dashes, instead of being longitudinal, are at right angles to the length. If the ordinary lamp of the galvanometer be replaced by sunlight or lime-light, the electro-magnets (M. Samuel points out) may be actuated directly without use of a galvanometer relay; Bell's selenium elements having an average resistance of only 150 ohms in sunlight, and 300 ohms in darkness.

AN evaporimeter with constant level has been recently described by Prof. Fornioni (*Reale Ist. Lomb.*, vol. xiv. fasc. x.-xi). It consists of an oblong wooden case with a brass spiral descending into it from a micrometric screw. The spiral carries at its lower end a small glass vessel which acts as feeder. A glass siphon extends outwards horizontally from the feeder, and has at its outer end a small cup, in which the evaporation takes place. As the water evaporates in the cup the feeder is lightened, and rises by action of the spiral, thus keeping the level constant. A fine layer of oil in the feeder prevents evaporation from its water-surface. There are guides to control the vertical movements of the feeder, which, moreover, are indicated by means of a weighted thread, affecting an external index on a disk. The graduation of the instrument is expressed in millimetres of the height of water in the evaporating vessel.

SIGNOR MAURI (*Riv. Sci. Inst.* No. 11) obtains an economical and very compact battery carbon, intimately united with the electrode, as follows:—Finely-powdered graphite is mixed with an equal weight of sulphur (which should be free from carbonates), and the mixture is heated in an iron vessel until complete fusion of the sulphur. The temperature should not be raised beyond 200°. When the mass is fluid it is poured into a suitable metallic mould, and a thick copper wire, bent zigzag, is quickly inserted, a part being left projecting. The mass is let cool slowly: then it is easily drawn from the mould and is ready for use. These carbons have a conductivity practically equal to that of retort carbon, and are more electro-negative, consequently better adapted for electromotive force. Coke-powder cannot be substituted for graphite, because it has too little conducting power. By increasing the proportion of sulphur, the resistance may be increased at will, and strong resistances may be thus easily prepared in place of resistance-coils of copper wire. (S. Mauri further indicates a way of utilising graphite in construction of a miner's fuse.)

REPEATING Mercadier's experiments in which an intermittent beam meets smoked a surface within a glass tube containing aqueous or ammoniacal vapour, and furnished with an ear-tube, Prof. Mugna lately (*Riv. Sci. Ind.* No. 11) made the effects much better heard by attaching a small microphone to an elastic membrane closing the tube; and it was possible to operate at such distance from the interrupting apparatus, that its noise was no longer disturbing. Prof. Mugna further experimented by suspending horizontally from a cocoon-fibre, within a glass case, a short fine glass rod, with terminal laminæ of card or glass, or very fine metallic foil. An intermittent beam sent against one of the laminæ when they were in a position parallel to the wheel drove the system round in direction of the beam, indicating (the author considers) a direct action of the latter. An air-current due to thermal action should produce the opposite motion. Besides, the phenomenon is still better when the air is rarefied.

IN a note to the Vienna Academy, Dr. Margules calls attention to the beautiful figures that are produced in glycerine, when the liquid is moved in a regular way, by rotation of a disk in contact with it. These figures afford an insight into the form of the surfaces and paths of the currents. They are due to the water contained in the glycerine.

THE method described by Herren Kirchhoff and Hahnemann last year for determining the heat-conductivity of metals, has been applied by them (*Wied. Ann.*, No. 7) to three varieties of iron, and to lead, tin, zinc, and copper; and the electric conductivity of these metals has also been measured. The conclusion is that the ratio of these conductivities is in general constant in these different metals, with exception of iron, and it is thought the exception may be connected with magnetic properties. Herr H. F. Weber's result disagrees with this, for he finds the ratio to be a linear function of the product of specific heat and density. The authors are unable to discover the cause of this discrepance.

AN initial attempt to elucidate the ratio of the specific heat of liquid organic compounds to their composition has been made by Herr von Reis (*Wied. Ann.*, No. 7). It appears from his researches that the difference of the molecular heat of homologous compounds at 20° boiling point, and from 20° to 100°, is very regular: in the former case it is 8·0 and in the latter 7·5.

Alcohols form an exception, having a comparatively high specific heat; they gave the differences 9·7 and 8·5 respectively. Isomeric substances of similar composition have the same molecular heat, while those of unlike composition have a different. In the tables which give carbon and hydrogen differences there are exceptions along with regularity. For a right development of the theory Herr von Reis feels that more extended observation is necessary.

THE idea of qualitative analysis of substances by microscopical examination of crystalline forms is worked out to some extent by Herr Lehmann (*Wied. Ann.*, No. 7). A shallow watch-glass is substitnted for the cover glass, and serves for turning over in various ways the crystals which form in the inclosed solution. The domain of regular forms is avoided as unsuitable, and only irregular forms observed—the so-called growth-forms, crystal skeletons, trichites, &c., produced by acceleration of crystallisation, viscosity, and so on. For details of Herr Lehmann's method and apparatus we must refer to his paper.

HERR SCHULLER has lately described to the Hungarian Academy of Sciences (*Wied. Ann.*, No. 7) a mercury air-pump which works automatically, and in which all greased glass combinations are dispensed with, the hermetic closure being effected with only glass and mercury. The evacuating power of the apparatus was not exactly measured; there are proofs that it is high.

MR. J. MILNE has written a careful account of the vertica and horizontal motions accompanying the earthquake of March 8, 1881, in Japan. This is believed to be the first earthquake in which a complete continuous record of both components of the motion has been obtained for a period exceeding twenty-five seconds. The actual maximum displacement appeared to be about 1·33 millims., recurring at the rate of about seven vibrations in five seconds. From the phenomena of this shock, and from some experiments on artificial earthquakes produced by letting an iron ball weighing about one ton fall from a height of about thirty-five feet, Mr. Milne argues that the waves that are felt are *transverse* to the line of propagation of the shock.

BIOLOGICAL NOTES

RELATIONS BETWEEN THE CRANIUM AND THE REST OF THE SKELETON.—These relations form the subject of a paper by M. Manouvrier, read at the last meeting of the French Association. The following are the author's conclusions:—1. The weight of the cranium varies, in a general way, with the weight of the skeleton, but not proportionally, like the weight of the brain. 2. The weight of the skeleton, less the cranium, in a given race, varies nearly in proportion to the weight of the femur. 3. The weight of the cranium is greater relatively to that of the femur, the lighter the latter is. 4. The weight of the cranium is much more considerable relatively to that of the femur in woman than in man. 5. This sexual difference is so pronounced that it constitutes one of the best secondary sexual characters. About 82 women in 100 have the cranium heavier than the two femurs, while 82 men in 100 have it lighter. 6. The lower jaw is heavier relatively to the cranium in the anthropoids than in man, is inferior than in civilised races, in man than in woman, and in the adult than in the child. 7. The weight of the cranium is smaller relatively to that of the lower jaw, the heavier the latter is, &c.

THE COLOUR CHANGES OF AXOLOTL.—Prof. Semper has lately examined axolotl with regard to the influence of light on its colour (*Würzburg Phys. med. Ges.*). When young axolotl are reared in darkness they become quite dark; nearly as dark in red light; in yellow, on the other hand, pretty bright; and brightest in bright daylight. The difference is connected not only with the chromatic function found in various degrees in all amphibia, but on pronounced formation of a peculiar diffuse yellowish green colouring matter, increase of white, and diminution of dark chromatophores. Further, when axolotl are exposed to daylight in white dishes covered with white paper, much less dark pigment forms in them than when they are kept in white dishes without a paper cover (other things equal); though in the latter case they are apparently exposed to the most intense light; these darker axolotl are, however, still much brighter than those reared in red light or in darkness. Since (as experiment showed) the white covering paper let through much light, but very little of the chemical rays, it appears that chemical rays play no part in the formation of pigment. But the causes of the whitening in bright daylight and the darkening in absence of light remain unknown as before.

SIREDON LICHENOIDES.—Mr. W. E. Carlin publishes in the June number of the *Proceedings* of the United States National Museum some very interesting details about this remarkable form. Its chief habitat is a body of water some two and a half miles in circumference called Como Lake. This has no known outlet, but is fed by a perennial stream of pure spring water. The lake is shallow, and its water very strongly impregnated with an alkali; it is very disagreeable to the taste. The Siredon never enter the freshwater stream; they abound in the alkaline waters of the lake in immense numbers. When about one hundred and fifty were placed in fresh water they seemed to suffer no inconvenience, but it had a remarkable effect in hastening their metamorphosis into the Amblystoma form. Of an equal number kept in fresh water and in the lake water, quite a change occurred with the former after twenty-four hours, while the latter showed no change after several days of captivity. Those that were kept well fed in jars usually began to show a slight change in from two to three weeks, and all of them completed the change into the Amblystoma inside of six weeks, while in some kept, but not specially fed, there were but three changes in three months. Specimens kept in captivity became quite tame, soon learning to know that tapping the jar in which they were, meant a fly, and, rising to the surface, would snap at whatever they saw first, pencil or fly.

FISH MORTALITY IN THE GULF OF MEXICO.—We glean a few more particulars as to this strange mortality from the June *Proceedings* of the United States National Museum. The fishing interest of Key West is an important one, supplying thousands with the means of subsistence. The fishermen state that a volcanic spring exists, the waters from which are of a high temperature. The polluted waters are of a red brick colour; their influence is seen for a distance of 200 miles. A scant supply of sea water from the Gulf of Mexico sent to Washington was examined by Mr. F. M. Endlich of the Smithsonian Institution. That in which the fish died (A) contained a large quantity of algæ and infusoria, and the pure water (B) had none. They gave the following analysis:—

	A.	B.
Spec. grav.	1·024 ...	1·022
Solids per cent.	4·0780 ...	4·1095
Ferric compounds per cent. ...	0·1106 ...	0·0724
Injurious organic matters ...	ratio = 3 ...	= 2

Even on spectroscopic analysis Mr. Endlich could not find in A any mineral constituent which could noxiously affect the fish, and he thinks that death must be caused by parasitic algæ, while Surgeon Glazier agrees with the prevalent opinion that the catastrophe is due to the salt water being impregnated with gases discharged from volcanic or geyser-like springs. During November last the waters of Tampa, Sarasota, and Charlotte Harbour were covered with thousands of dead fish, and the stench was quite overpowering.

THE BLOOD OF INSECTS.—Operating with the larva of *Oryctes nasicornis*, M. Fredericq has observed (*Bull. Belg. Acad.*) that the blood of the animal, drawn off in a small glass cannula, is a colourless liquid, but on exposure to the air presently takes a decided brown colour, and coagulates. The coloration he regards as a purely cadaveric phenomenon. The substance which becomes brown is probably formed in the moment of coagulation, and does not serve in the body as a vehicle between the external air and the tissues, like *hæmoglobin* in Vertebrates and many Annelids, *hæmocyanin* in Crustaceans, &c. When the larva is kept a quarter of an hour in hot water (50° to 55°), the blood extracted does not coagulate or become brown. Once the substance which browns is produced, even a boiling temperature does not prevent its browning. The brown substance once formed is very stable, not being decomposed either by acids or alkalies, and not made colourless by being submitted to vacuum or kept in a closed vessel. The existence of an intermediary in insects corresponding to hæmoglobin M. Fredericq thinks very problematical in view of the anatomical system, letting air penetrate into the heart of the tissues.

NEW PYCNOGONIDA.—The result of the examination of the collection of Pycnogons made during the cruise of the U.S. steamer *Blake* by Edmund B. Wilson, has just been published as No. 12, vol. viii. of the Harvard College Museum *Bulletin*. This collection was found to possess features of considerable interest, and though the species in it were few, some of them

were of remarkable size, quite colossal in comparison with shallow water or littoral forms. Of the three species of Colossendeis, two of which are described as new, the smallest has a span of 14 cm. between the tips of its outstretched legs, while the largest has an extent four times as great. A new genus (Scæorhynchus) has been established for a species with a span of 19 cm., a gigantic size as compared with the dimensions of its nearest allies. The most abundant species of Nymphon is the largest of that extensive genus, and one species of a new genus (Pallenopsis) is more than twice as large as any of the species of allied genera, such as Pallene, which are known only from the littoral zone. It is further interesting to note that in a number of forms the visual organs (ocelli) are either rudimentary and destitute of pigment, or are entirely absent. In Pallenopsis, however, the ocelli are relatively of unusually great size. The species of Scæorhynchus and Colossendeis show clearly from anatomical evidence the complete independence of the accessory legs and the first pair of ambulatory legs, as had been already proved by Dohrn from embryological data. In all cases the palpi and accessory legs are supplied with nerves from the same ganglion, and this latter shows in the adult no indication of being composed of two coalesced ganglia. But Dohrn states that there are in the larvæ of Achelia two ganglia. This question is of great interest, having a direct bearing on the affinities of these Pycnogons with the Arachnids. Mr. Wilson describes ten species, of which one half are given as new, and with figures.

New Zealand Desmids.—As a contribution to our knowledge of the pretty green unicellular algæ known as Desmids, which are to be met with in New Zealand, Mr. Maskell's paper in the recently-published volume of the *Transactions* of the New Zealand Institute is most welcome. It would seem to render more than probable the idea that these minute algæ are to a large extent cosmopolitan. The author is evidently under great disadvantage as to identifying the species he meets with, but this is to a great extent done away with by his fairly careful descriptions and accurate (as to outline) figures. He enumerates between sixty and sixty-five species, some of which are very noteworthy and fine additions to the list of Desmids; thus *Aptogonum undulatum* is a highly interesting new species. *Triploceras bidentatum* is not only a very distinct, but also a very noble, new species, and equally distinct as a species is his *Closterium selenæum*. Doubtless a more prolonged search in fresh localities will enable the author to add many old and new species to the list. He may feel sure that his further researches will be looked for with interest by those working at the freshwater algæ in Europe.

Protoplasm Stained whilst Living.—Mr. L. F. Henneguy publishes the result of some experiments made on living infusoria, in which he confirms the observations of Brandt, made in 1879, that an aqueous solution of aniline brown, known in commerce as Bismarck brown, will give an intense brownish-yellow colour to the protoplasm of the infusoria without in any way interfering with their enjoyment of life. The coloration first appears in the vacuoles of the protoplasm, then this latter is itself stained, the nucleus being most generally not at first coloured, and so being made more conspicuous. Experiments made on vegetable protoplasm seemed to exhibit the same result.

LARGE TELESCOPES[1]

THE small amount of work accomplished with large telescopes has often been the subject of unfavourable comment. This criticism applies with especial force in America, where there are nearly a dozen telescopes having an aperture of a foot or over, besides two of the largest size now in course of construction, and two of twenty-six and twenty-four inches aperture which are unmounted and have been for several years perfectly useless. Among so many it seems as if one might be spared for a trial of the following plan, which, if successful, would produce at a small expense far more work than could be obtained with a mounting of the usual form.

Suppose that the telescope is placed horizontally at right angles to the meridian, and that a plane reflector inclined to its axis by 45° is placed in front of it. This reflector may revolve around an axis coinciding with that of the telescope. Such a mounting has been used in transit instruments, and gives much satisfaction in the meridian photometer of the Harvard College Observatory. The principal difficulty with a large instrument would lie in the flexure of the reflector. This difficulty has however been overcome in a great measure in reflecting telescopes by various ingenious devices. In the present case, since the reflector rotates only around one axis instead of two, the problem is much simplified. A slight motion at right angles of perhaps 5° would be a great convenience, as will be shown below, and would probably be insufficient to materially affect the flexure. It may be said that it is more difficult to make a plane surface than one that is curved. But the principal effect of a slight curvature would be to change the focus of the telescope, the aberration being much less than the effect of the varying flexure. Let us admit, however, that the best definition cannot be obtained, in considering the purposes to which such an instrument could be applied without disadvantage.

Many advantages will be apparent on comparing such a mounting with an equatorial. Great steadiness would be secured, since the mirror would be the only portion moved, and this would be placed directly upon a low pier. Instead of a large and expensive dome which is moved with difficulty, the mirror would be protected by a small shed, of which the roof could be easily removed. It would therefore be opened and ready for use in a very short time, and would quickly take the temperature of the surrounding air. The object-glass would be mounted directly upon a second pier, and, as it would not be moved, would be in very little danger of accident. The tube could be made of tin or other inexpensive material, as its flexure is of no importance. It could easily be protected from the changes of the temperature so troublesome in the tube of a large equatorial. If preferred it might even be exhausted of air, or filled with hydrogen, and the effect of the changes of temperature thus greatly reduced.

The eyepiece could be mounted on a third pier, and would be so far distant horizontally from the mirror and object-glass that there is no reason that it should not be inclosed in a room which may be warmed. The comfort in winter of working in a warm room will be appreciated by those who have used a large telescope in a cold climate. The result is sure to be an increased precision in the observations, and a possibility of prolonging them over longer intervals. A similar effect is produced by the constant direction of the line of sight. No especial observing chair is needed. There is no limit to the size of the attachments which may be made to the eyepiece, since they need not be moved. This is a great advantage in certain spectroscopic and photometric measurements. A strong wind interferes seriously with many observations, as it is impossible to make a telescope so stiff that it will not be shaken by sudden gusts. In the plan here proposed the mirror alone is exposed, and its surface is too small to give trouble.

By means of a long handle the position of the mirror may be regulated from the eye-end, and the declination of the object observed read by small telescopes. If the mirror can be moved at right angles to the meridian 5° from its central position, an object at the equator may be followed for forty minutes, and other objects for a longer period. Without this motion an object may be followed for three or four minutes by moving the eyepiece alone. Clockwork may be applied to the mirror, or less easily to the eyepiece. The focal length may be increased almost indefinitely if desired, and certain advantages will be thus attained in the diminution in the defects of the object-glass, although those of the reflector will not be affected. If the telescope is to be erected at a great elevation the advantages of the present plan are at once apparent. Many nights of observation would be secured which otherwise would be lost owing to the wind and cold. The simplicity in the construction of the building would be a great advantage, as a large dome in so exposed a situation would be kept free from snow with much difficulty, and might be a source of danger in winter storms. If found impracticable to observe during the winter, it would be possible to have a duplicate mounting below, and remove the lens and mirror from one to the other.

It is evident that the saving of cost would be very great, not only in the observatory building and dome, but in the tube, observing chair, clockwork, &c.

If a reflector could be constructed whose surface was the portion of a paraboloid whose abscissa equalled that of the focus, the instrument could be much simplified. No object-glass would then be required, the reflector taking the place both of mirror and lens. All the light intercepted by the objective would thus

[1] By Edward C. Pickering, communicated by the author.

be saved, and but a single surface need be adjusted and corrected. With the advance in mechanical methods this does not seem wholly impracticable, especially with a mirror of long focus. Since the final correction must always be made by hand, it makes but little difference what is the exact form of the surface.

In any case it would be a great advantage that the mirror could be reground, repolished, or resilvered without moving it from its place. It would only be necessary to place it horizontally, and the grinding machinery could be kept permanently near it. If plane, the perfection of its form could also be tested at any time by setting it on edge, and viewing the image it reflected by a collimating eyepiece attached to the large telescope. Another method would be to place a heliotrope a few hundred yards to the north or south of it, and the light from this would form an excellent artificial star, available whenever the sun shone.

The greatest advantage is the rapidity with which observations could be made. No more time would be lost in identification than with a transit instrument, so that a large number of objects could be examined in the course of a single hour. Any one who has worked with a large telescope knows how much time is lost in opening and closing the dome and in finding and identifying minute objects.

Let us now consider to what purposes a large telescope mounted as suggested might be applied.

1. Sweeping. For the discovery of new objects this mounting presents especial advantages. It might be used for the detection of new double stars, of nebulæ, of red stars, or of objects having singular spectra, as planetary nebulæ, banded stars, and variables of long period. Suppose that the field of view had a diameter of somewhat over one minute of time, and that a small motor was attached to the mirror which would move it uniformly over 5° in declination in this time, and then bring it quickly back to its first position. The observer would then have presented to him a series of zones 5° long and one minute wide. The sweeps should overlap by a small amount, so that the entire region could be covered in a single evening. The observer could have a few seconds rest between each zone, while the motion of the mirror was reversed. If an object of interest was suspected, it could be located by merely noting the time at which it was seen. The right ascension would be given directly, and the declination would be found by interpolation from the time of beginning and ending the sweep. An examination of the object and a determination of its exact location should be made on another evening.

2. Measures of position. For many purposes positions could be determined with this instrument as in a transit circle. It would generally be better however to make the measures differential, leaving the mirror at rest and observing the transits of the object to be determined and of two or more companion stars. The method of the ring micrometer might be employed, or some modification of that with inclined lines. In the latter case the zero of position could be found by the transit of preceding stars, by setting the reticule by a divided position circle, or perhaps better by keeping it in a fixed position, determining the direction of the lines once for all, and applying a correction for the declination of the object observed. Stars could be compared differing nearly a degree in declination, as the eyepiece could be moved without danger of disturbing the reticule. For the same reason the star could be followed for three or four minutes, and its transit over a great number of wires observed. It is here assumed that the distortion produced by the mirror is not very great. A slight distortion would do little harm, as it would be the same for all stars of equal brightness. If the stars differ greatly in brightness, the observer should determine his personal equation between them in any case, and the same operation would eliminate the effect of the distortion. The large aperture of the instrument would permit the observation of stars quite beyond the reach of any meridian circle. The faintest asteroids could thus be readily measured, and could probably be followed in many cases on successive evenings to their stationary points. Zones of stars could be observed very conveniently for the formation of charts or catalogues, for the discovery of asteroids, stars with large proper motion, &c.

Probably the definition could not be sufficiently good for the measurement of the closer double stars, but if clockwork was attached, faint companions could be measured, or approximate positions of the coarser pairs determined very rapidly. The positions of nebulæ could also be observed with a view to detecting their proper motion. Stars having a large proper motion might be observed, and the observations so arranged that any very large parallax would be detected. A similar search for a large parallax of variable stars, short-period binaries, minute planetary nebulæ, or stars having singular spectra, might lead to interesting results. The argument that no ordinary star is very near does not apply to such objects.

3. Spectroscopy. The increased dimensions which could be given to the spectroscope, and its steadiness, would compensate in a great measure for a defect in definition. By Zöllner's reversion spectroscope the slit might be dispensed with, and also the necessity of clockwork. So many stars could be observed in a single evening that systematic errors could be in a great measure eliminated, and as the spectroscope would not be moved, we should have a great assurance that the deviations were real. Of the 6000 nebulæ hitherto discovered we know nothing of the spectrum of more than 300 or 400, while the observation of all the others with a large horizontal telescope would not be a very formidable undertaking. It would also be interesting to observe the spectra of all the clusters. It is possible that some may consist of stars having singular spectra, or even of disconnected nebulous masses, in fact forming clusters of planetary nebulæ. The interesting discovery by Dr. Copeland that Burnham's double nebula in Cygnus is gaseous, shows the same tendency to aggregation in these bodies as in stars. Observations of the spectra of all the red stars and variables would also probably lead to interesting results.

4. Photometry. Should the instrument be devoted to photometry numerous problems suggest themselves. Variable stars could be observed near their minimum when too faint to be identified with an equatorial without great loss of time. Faint stars in zones or faint companions to bright stars could be measured very rapidly. The relative light of all the asteroids would be an interesting problem. Many coarse clusters appear to consist of stars of nearly equal brightness. Their light compared with their distances apart might aid our study of their formation. Another useful investigation would be to measure the brightness of all the nebulæ.

In the application of physics to astronomy doubtless many other problems will suggest themselves. Thus no satisfactory results have been obtained in the attempt to measure the heat of the stars with the tasimeter. The use of this instrument would be vastly simplified if it was placed on a solid pier near the ground, was not moved during the observation, and could be perfectly protected from other changes of temperature than those which it was intended to measure.

As either of the problems proposed above would occupy the time of a telescope for at least one year, it is obvious that there could be no difficulty in keeping such an instrument occupied indefinitely.

The horizontal mounting is especially adapted to an elevated position, and would permit the use of a telescope where an equatorial mounting would be quite impracticable. On the other hand, to an amateur, or for purposes of instruction, an instrument which could be set quickly from one object to another, and where the observers need not be exposed to the cold, would offer many advantages. The impossibility of observing far from the meridian would be less important with a large instrument, where the number of objects to select from is very great.

There are certain purposes to which this mounting could not be advantageously applied. The study of close double stars and other objects requiring long examination and very perfect definition could be better left to other instruments. The sun, moon, and planets can also generally be better observed off the meridian. If, however, the entire time of an instrument can be employed to advantage, and it can collect several times as much material as an instrument of the usual form, it is no evidence against its trial that there are certain problems to which it cannot be advantageously applied.

The working force required for such an instrument should consist of at least one observer, an assistant to record, and a number of copyists and computers to prepare the working lists, reduce the observations, prepare them for the press, and read and check the proof-sheets. A large volume of valuable observations could thus be produced every year, which would require at least double the time and money to produce by the same telescope mounted equatorially. The difference in the amount of work will be evident when we compare the number of objects observed with a transit instrument per night, with those observed with an equatorial. A hundred objects in various declinations might be examined in a single evening, while it is seldom that the same number could be identified and measured by an equatorial in a week.

SOLAR PHYSICS—THE CHEMISTRY OF THE SUN[1]

Tests afforded by the Stars

WE will now see how the views which have been put forward are borne out by the facts which are presented to us by the stars. There is no need to occupy much time, in fact reference need only be made to Dr. Huggins' paper which was communicated to the Royal Society in the course of last year, and with that paper we may compare some earlier writings. It was as early as 1864 that Dr. Huggins, who was then associated with the late Dr. Miller, called attention to the intensely strong lines of hydrogen visible in the hottest stars.[2] In this paper they pointed out at the same time that other metallic lines associated with those lines of hydrogen were thin and faint. It has been already mentioned that, as we have independent evidence that these stars are hotter than our sun, we had strong grounds for believing that here we were in presence of a result brought about by a higher temperature, associated as it was with a simpler spectrum, and, therefore, presumably with simpler constituents. We need not stop now to discuss the objection which has been put forward by an ingenious person ignorant of the facts, that the broadening of these lines may not be due to an increase of temperature at all, but really to a very rapid equatorial rotation of the star. This is a fair sample of one of the classes of objections one has to meet. Of course it is at once put out of court by the fact, also stated by Dr. Huggins, that, associated with the thick lines, are excessively thin lines. Any enormous equatorial velocity of the star should have made all the lines thick, but this is not the fact. Now we have only two lines in the solar spectrum at all comparable in thickness with these hydrogen lines in the hottest stars, taking Sirius and α Lyræ as types.

In a paper communicated to the Royal Society in 1876[1] it was remarked that laboratory work indicated the possibility that line-spectra might, after all, really not result from the vibration of similar molecules; and at that time the evidence seemed to be so clear in the case of calcium that it was pointed out that the time had arrived when evidence touching calcium itself ought, if possible, to be obtained from the stars by means, of course, of photography, because the part of the spectrum in question—the region of H and K—is exceedingly faint in the case of the stars.

Why, it may be asked, was it important to get this evidence from the stars? I will read an extract from a book,[2] published some years ago, which puts this view forth:—"It is abundantly clear that if the so-called elements, or, more properly speaking, their finest atoms, those that give us line-spectra, are really compounds, the compounds must have been formed at a very high temperature. It is easy to imagine that there may be no superior limit to temperature, and, therefore, no superior limit beyond which such combinations are possible, because the atoms which have the power of combining together at these transcendental stages of heat do not exist as such, or rather they exist combined with other similar atoms at all lower temperatures. Hence the association will be a combination of more complex molecules as temperature is reduced, and of dissociation, therefore, with increased temperature there may be no end."

That was one point.

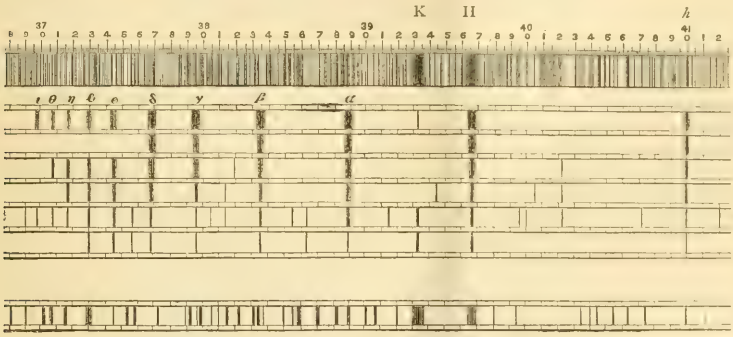

FIG. 43.—Stellar spectra (Huggins).

Here is the next point which made an appeal to the stars so necessary. "We are justified in supposing that our terrestrial calcium once formed is a distinct entity, whether it be an element or not, and, therefore, by working at terrestrial calcium alone we shall never know, even if its dissociation be granted, whether the temperature produces a simpler form, a more atomic condition of the same thing, or whether we are unable to break it up into $x + y$, because in our terrestrial calcium, assuming all calcium to be alike, neither x nor y will ever vary; but if calcium be the product of the condition of relatively low temperature, then in stars hot enough to enable its constituents to exist uncompounded we may expect these constituents to vary in quantity; there may be more x in one star, and more y in another. If this be so, then the H and K lines would vary in thickness, and the extremest limit of variation will be that we shall have only H represented, or x in one star, or only K represented or y in another, and intermediately between those extreme conditions we have cases in which, though both H and K are visible, H is thicker in some and K is thicker in others."

What, then, are the results of this appeal to the stars which Dr. Huggins has made with such splendid success? We have in the hottest stars a spectrum so regular, so rhythmic, that it seems impossible not to consider it as produced either by the same substance or by substances closely allied. Is it by mere accident that some of the *least* refrangible lines coincide with those of hydrogen? is it by mere accident that the most refrangible lines have never been seen except in these stars? One of them coincides with H, one of the lines which still remain thick in the sun, and with which we find a fine line of hydrogen to be coincident. Fig. 43 is a copy of Dr. Huggins' diagram, to which reference has been made. At the top is a portion of the solar spectrum in the violet and ultra-violet, and next is the spectrum of the hottest star, α Lyræ. This spectrum, it will be seen, is simpler even than the spectrum of the solar prominences, and not only is there this wonderful simplicity, but note the exquisite rhythm by which the distance between the lines gradually increases as we go from one end of the spectrum to the other. Note also that the least refrangible line shown on the diagram is coincident with *h* in the violet part of the solar spectrum, and that the next line is coincident with the line H, to which reference has been made in the notes I have read. Note also the relative intensities of the lines H and K in the sun, in which their intensities are about equal, and in η Ursæ Majoris, in which K is altogether absent. These are the first points in this diagram to which attention must be drawn. There will be other points as we proceed further.

But in descending from the general to the particular Dr.

[2] "Studies in Spectrum Analysis," p. 196.

Huggins writes:[1]—"The spectrum of Vega may be taken conveniently as typical of the whole class of white stars, so that the distinctive features of the other stars of this class may be regarded as modifications or departures from this common typical form." He then adds: "There are principally three directions in which changes take place"; one of these consists "in the presence or absence of K, and if present, in its breadth and intensity relative to H." He goes on, "One of these modifications, which possess great suggestiveness, consists of the absence, or difference of character presented by the line K. In all the stars of this class this line is either absent or is very thin as compared with its appearance in the solar spectrum, at the same time that H remains very broad and intense. In the spectrum of Arcturus, a star which belongs to another class which includes our sun, this line K has passed beyond the condition in which it occurs in the solar spectrum, and even exceeds the solar K in breadth and intensity." Arcturus is given in the lower part of the diagram, and it will be seen that there K is relatively thicker than H; and also that with this relative increase in the thickness of K we get a considerable complexity of spectrum, very much more approaching the solar spectrum in the number of lines that we have to contend with. But at the same time I should point out that the positions of these lines vary from the positions of lines in the solar spectrum. "The spectra of these stars," Dr. Huggins continues, "may therefore be arranged in a continuous series, in which first we find this line to be absent. Then it appears as an exceedingly thin line. We then pass to another stage in which it is distinct and defined at the edges; in the solar spectrum it becomes broad and winged, and lastly in Arcturus there is further progress in the same direction, and the line, now a broad band, exceeds in intensity H." Absolute continuity we see in the story which Dr. Huggins brings us with reference to this concrete case of H and K in the details and in general. Well might Dr. Huggins ask after this: "Do these modifications not represent some of the stages through which our sun has passed?" In another part of his paper he uses the term "life changes." Now the life of a star is its temperature, and all these changes must have been produced by the running down of temperature, and I think the simplest view to take, limiting ourselves to the concrete change of H and K, is that the substance which produces K has been formed at the expense of the substance which produced H, and the reason that we see these two lines in calcium when a high temperature is employed is that we reveal the presence of these true root-forms. There may be very many more difficult explanations, but that I think is the simplest one to which one is driven by the logic of facts.

The appeal to the stars, then, I think, amply justifies the prediction which I based upon the comparison of solar with terrestrial phenomena, and, therefore, helps to show that the basis on which those predictions were founded had at all events some little glimmering of truth about it. I think also that it increases the dissociation stages through which we must assume the vapours of our so-called elements to pass when higher temperatures are employed in succession.

So much then for the tests which we have been able to apply to these views by means of Dr. Huggins' remarkably beautiful researches.

The wide departure of stars hotter presumably than the sun (taking the centre of gravity of the absorption, so to speak, as the indication of temperature) from the solar type shows that there is much more work to be done in this field. The success of my former prediction emboldens me to make another one. *It will in all probability be found that the remaining thick lines in stars of the Sirius type are represented in many cases by the lines brightened in solar prominences.*

Tests afforded by the Phenomena of Fluted Spectra

So far we have dealt with line spectra, but we must not limit ourselves to a consideration of this class of spectra if we wish to test this view to the very bottom, as it is our bounden duty to do. We have therefore to ask ourselves the question with reference to other regions of spectrum analysis beyond that particular part which we have been discussing: Is the evidence to be got from those other regions the same? Does it tend in the same direction as the evidence which has been supplied from the consideration of the highest possible temperature in our coils and in the sun? I have no hesitation in saying that, so far as I know, the evidence is absolutely strengthened by a consideration of the low temperature phenomena observed spectroscopically.

[1] *Phil. Trans.*, 1880.

In fact the view was started very many years ago by observations at much lower temperatures than those we have been considering. Plücker and Hittorf, who worked at spectrum analysis before Kirchhoff and Bunsen, were bound to acknowledge that some of the substances with which they dealt had really two distinct spectra, which they called spectra of the first order, and spectra of the second order, which spectra changed as the temperature they employed changed; and although they came to the conclusion that these simply represented allotropic conditions, not molecular dissociation, I think when one comes to inquire into the subject thoroughly, one will find there cannot be any very great difference between those two considerations. In fact the question of double spectra, which has been fought for many years, but which I think is now nearly at rest, was started by the observation of Plücker and Hittorf. Of course the view they put forward was objected to very strongly, and was met by the assertion that they were misled by impurities in the substances which they experimented on. For instance, they found a second spectrum for hydrogen; this second spectrum, which had a very special character of its own, was referred to acetylene. Soon after, a part of the carbon spectrum which was entirely different from the second spectrum of hydrogen, was referred to acetylene. So that those gentlemen who saw in these phenomena nothing but impurities were perfectly content to give an explanation which would be quite right, provided hydrogen and carbon could only be supposed to have one spectrum; the *impurity* acetylene having two. Later work has shown that it is too *coarse* a view to think that the fluted spectra which represent the spectra of the first order of Plücker really represent the vibration of one molecule in the same way that the line-spectra were supposed to do. Evidence has been accumulated which indicates that in some cases where we get three or four flutings, those three or four flutings which can be seen one by one are inversely intensified, in precisely the same way that various lines can be seen one by one, or almost one by one, and inversely intensified. It seems as if even flutings cannot be considered to be simply due to the result of one special kind of allotropism, but probably represent several.

Let me give a figure or two to represent this point.

An application of the principles referred to in Figs. 32 and 33 will readily enable us to understand that a substance may give us a particular fluting at the lowest temperature, represented by the furnace C, a different fluting in the furnace B, and finally a line at the highest temperature afforded by the furnace A, as shown in Fig. 44, and that at intermediate temperatures its spectrum may consist of mixtures in varying proportions of each of these constituents, and it will also be seen that the line produced by the highest temperature can never be seen together with the lowest temperature fluting, unless the fluting produced by the intermediate temperature is present also. Fig. 45 shows the facts actually observed when the spectrum of carbon is photographed under various conditions of temperature.

The results are strikingly suggestive, as we have a compound origin to the two sets of flutings shown.

But there is a lower region yet, a region in which much work has been done which seems to show that before the substance is fit to give us flutings, that it can still record for us—in a very feeble sort of way—it can yet record for us its vibrations by absorption at one end of the spectrum or at the other, so that the story of simplification is really intensified when we leave the high temperature spectrum, and it seems as if the first effect produced by the action of heat on any substance is to give us general absorption which breaks up into absorption in the red and absorption in the blue, and then we get a series of flutings more or less complex according to the temperature of the body; and then when we have passed from this stage we get the series of line spectra to which I have drawn attention. Again, in passing from a low temperaure to a high temperature, so far as I can see there is absolutely no break, nor is there any difference of kind that we are acquainted with in the passage from a compound body and the passage from a known form of, let us say, gold or silver, at a low temperature, to that same substance at a higher temperature.

If we assume that these various spectra are really due to different molecular aggregations, we shall have the following series, going from the more simple to the more complex:—

First stages of complexity of molecule	Line-spectra.
Second stages...	Channelled space or fluted spectra.

Third stage	Continuous absorption at the blue end not reaching to the less refrangible end. (This absorption may break up into channelled spaces.)
Fourth stage	Continuous absorption at the red end not reaching to the more refrangible end. (This absorption may break up into channelled spaces.)
Fifth stage	Unique continuous absorption.

So that the story is one of absolute conformity, absolute continuity from one end of the series to the other; but on this subject I need not say more, because my friend Capt. Abney will have a great deal to say about the red molecules and blue molecules when he comes to deal with the red end of the spectrum, and I may safely leave this part of the subject in the hands of one who has so brilliantly distinguished himself by his investigations upon it.

Replies to Objections

Now I think it is time that I should reply, or attempt to reply, to some objections that have been made to these views. So far as I can gather, the serious objections which have been made are not many, but some of them are objections to which considerable value should be attached. The chief one now

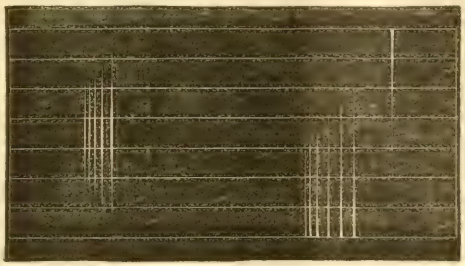

FIG. 44.—Diagram showing the action of three different temperatures on a hypothetical substance assuming three stages of complete dissociation; and also of intermediate temperatures at which the vapours are only partially dissociated.

urged is that one is misled in the conclusions that one draws from these observations of spots and storms by the fact that the solar lines corresponding with the lines which we consider to be common to two substances are really double, and that the lines common to two substances appear common simply because we have not sufficient dispersion to separate them. Now that is a very important objection indeed, but let us examine it. It has been pointed out that of the 62 iron lines which remained as the result of the purification of the first part of the map (between wave-lengths 39 and 40) only 18 were left; all the rest being found common, not only to two substances, but in a great many cases to four or six substances, and we found also that our rough observation-book, as we went on, suggested that the solar line was double; but if we had gone on in that way we should not have been able to produce a map at all, because there would have been few lines which were not complex, so that it would have been a piece of cowardice to remain there and not attempt to find out what it meant. Now let us suppose a great many of the solar lines are double. It is fair to assume that these double lines would be irregularly distributed throughout the spectrum. We cannot imagine some spiteful freak of nature choosing out to be double a particular set of solar lines which

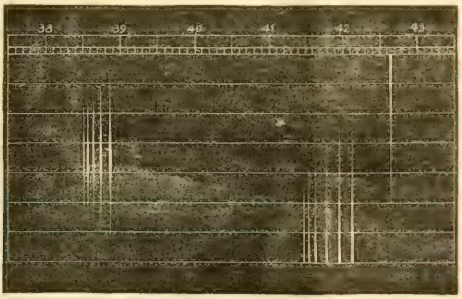

FIG. 45.—The photographed spectra of some carbon compounds.

some one should eventually find common to two substances; we must imagine an impartial distribution of double lines if we are to consider them as double. Now the argument we can bring against that is founded on this, that two things always hang together, the alleged complex nature of the line and the fact that this particular line is picked out for special prominence in spots and storms. For instance, take the line 4923·2 referred to in Fig. 41. If that line is double, and is one of two lines seen in flames, the probability that that line should be double, supposing that the solar line is double, would be as 2 to 1, but that line is picked out as 50 to 1 in the case of prominences. The betting in favour of the coincidence is not so great in the case of the spots, but when we come to the prominences, when we are dealing with 100 lines with the probability therefore of 50 double lines if they are equally distributed, and that every other line is double—when we come from 100 lines to 1, it is 50 to 1 against this particular line being double; and yet this is the particular line which we always find to be common to two substances when we really discuss the observations of the flames. I think then that the idea that these basic lines are simple creatures of the imagination, simply chance coincidences, will really not stand at all.

Prof. Young has lately brought forward this objection, although in 1872 he was the first to point out the very extraordinary fact as it appeared to him, and as it still appears to every one else, that an enormous number of coincident lines which he got from the tables extant at that time seemed to cluster round the bright lines seen in his observations. The credit of that is

undoubtedly due to Prof. Young, and although he has lately seen cause to withdraw somewhat from this first view of his, he is still driven to think that two of the most important lines in the solar spectrum, H and K, are really due to two substances—hydrogen and calcium. There is one more thing which must be said with special reference to this: the work is not to be negatived by a mere assertion that the line is double; it must in a great many cases be shown that it is a double-double or a treble-treble line. For instance, take the case of $b4$, which may very well be double for aught we know; that line is coincident, so far as we can make out with the means at our command, with magnesium, iron, nickel, uranium, chromium, and cerium. It will not do to limit oneself to the statement that these lines are double—they must really be perfect families of lines in order to prevent this explanation being, as I think it is, the more probable.

Another objection, again, a very important objection, is of a somewhat different nature, and may shortly be called the bell hypothesis. It is to the effect that these molecules, or atoms, are very extraordinary things indeed, as we can well imagine them to be, and that the spectrum which they produce depends entirely upon the manner in which they are struck; so that in fact it would seem at first useless to construct a map of any spectrum at all, for fear the substances we wish to observe in our laboratories should be struck in different ways and should render the map perfectly useless. I say the idea is really that the molecules struck differently would give us different spectra. Now if the difference were only slight, that would not much matter; it would be very difficult to withstand that hypothesis. But it must be remembered that in this work we are dealing with this extraordinary fact, that over the region which we have been specially studying there are no lines of iron common to spots and flames; so that if we had not any iron at all to experiment with we should be perfectly justified in asserting the iron lines in flames were produced by one substance and those in spots by another, because no two lines agree in *these* two spectra. The spectra are as distinct as the spectrum of magnesium and the spectrum of iodine, or any other two bodies. Now if the bell hypothesis is to explain that, it explains too much, because if it is true of any two bodies, it must be true of all bodies, and therefore all spectra are the result of the same thing struck differently, and spectrum analysis would then cease to be spectrum analysis, for it would simply record changes rung on the same molecule by the various methods of striking. Then again there is another thing to be said, that no statement of this bell hypothesis which I have heard gets us out of the difficulty that we are sinning against the law of continuity in advancing it, for the reason that if you begin with a known compound body, let us say, a salt of calcium, the change from a salt of calcium to calcium is the same in kind and about the same in degree as the change from one form of calcium to the other, if we can talk of different forms of calcium on the mere strength of spectroscopic work. I mean that there are more important changes to be got out of the observations of the metal calcium than there are to be got by passing from a salt of calcium to calcium; so that if the bell-hypothesis proves anything it proves that a compound body is a simple one.

It will be seen that the special import of these considerations lies in the question of the short lines; leaving all considerations dependent on long lines, by which the presence of impurities may be recognised, out of consideration altogether. But it may be further said that a method of purifying spectra and eliminating any spectroscopic defects which were due to the presence of

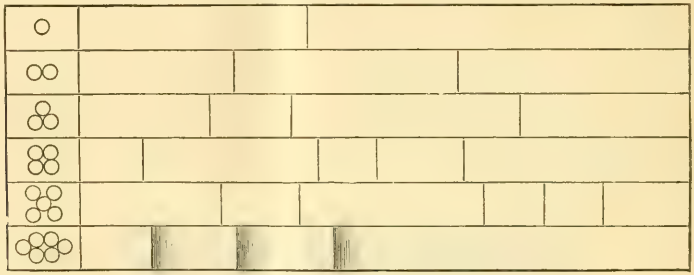

FIG. 46.—Diagram showing how the evolution of chemical forms may be indicated by their spectra.

impurities has been before the scientific world for some years, and so far as I know its validity has never been called in question. Where that method has been employed I believe it has been employed honestly, so that until that method is called in question by better work—and the work I know will be severe—I think we are bound to accept the results which have been obtained by it.

Then there are some theories which I might be permitted to say a few words about, but in reference to them I need only call attention to Dr. Schuster's admirable report on the progress of spectrum analysis, given to the British Association at the meeting at Swansea. It will be seen from that report that none of the theories which have been put forward really account for all the facts observed. It is shown that phenomena have been recorded which are not to be explained away by the bell theory or any other. Such a phenomenon, and a perfectly distinct one, is the change due to the thickness in the vapour. Changes also due to varying temperature and other causes have been seen, for which the theories in question do not account. Now changes in temperature may probably affect large reaches of the spectrum, but in the cases we have studied we got most diverse effects in lines so close together in the spectrum that it requires a considerable amount of dispersion to find out that they are really not single lines.

The New Theory of Chemical Evolution

What then is the view of the evolution of chemical species to which we are led by our study of the sun and stars? I think that after all it is but a slight expansion of the present chemical view. Chemists regard matter as composed of atoms and molecules, about which more presently. The view now brought forward simply expands the series into a larger number of terms, and suggests that the molecular grouping of a chemical substance may be simplified almost without limit if the temperature be increased. A diagram (Fig. 46) will show exactly what I mean. If we assume a very great difference in the temperature which can be brought to bear upon a substance we may assume that at the highest temperature we have, for simplicity's sake say, a certain line represented by a single circle; let us imagine the temperature reduced, we shall then get another spectrum, which we can represent by a double circle, if we like to assume that the evolution is one which proceeds by constant additions of the original unit. Coming lower down, we get another substance formed with a more complex spectrum represented by three circles; lower down still we have one represented by four circles, another by five, another by six, and so on. We might take another supposition, easier perhaps to some minds, and suppose that evolution proceeded, not by the addition of the initial unit, but by the constant doubling of the substance of the molecule itself. Instead, therefore, of our circles increasing by one, we shall have one, two, four, eight, sixteen, thirty-two, and it will be readily understood that if there are a considerable number of stages of temperature, both within our ken and beyond our ken, and if some substances form themselves perpetually by doubling, then the unit with which we can experiment at low temperature, call it the chemical atom or the chemical molecule, or what you will, must be a very complex thing indeed. If the lower spectrum represents that of a complex

body such as iron, or a salt of calcium, the upper spectra will represent those due to the finer groupings brought about by higher temperatures. We pass continuously, as in the sun and the stars, from complexity to simplicity, if we begin at the lower stages, and from simplicity to complexity if we begin at the higher stages of temperature.

Now, two questions arise here which I think it is important to discuss. Are we playing fast and loose, in such an hypothesis as this, with the ordinary course of nature's operations, or are we in harmony with her? Again, is it contrary to the view expressed by the greatest minds which have studied chemical phenomena? I think really the view is not inharmonious with those other views which we have gathered from other regions of thought and work; in fact, I think it derives its whole force from the fact that along many lines it runs parallel with the evolutionary processes in the different kingdoms of nature. I have another diagram which will show what I mean (Table I.). This diagram deals with a very simple case of evolution, and it deals with this evolutionary process, going along a single line. Of course we know very well that in the organic kingdom evolution always proceeds along many lines, but to simplify the problem I have dealt with one of the simplest that I can think of. Let us assume that in a certain hottest star there shall be two substances, which we will call a and b. They will first at the transcendental temperature which I assume, exist as separate entities; the temperature being then reduced, they probably will combine, and, instead of two atoms, a and b, we shall have one group of $a + b$. If the temperature is still further reduced, we shall get b combining with b; in that case we shall have a grouping consisting of $a + 2b$. Let the same operation be performed again, we shall then have $a + 4b$, combining into two groups of 2; we shall have what we can represent, in short, in chemical language ab_4. Now, having got our ab_2, having got our temperature reduced, let us assume that ab_2 is now the substance linked on to give a greater complexity, instead of b or $2b$ merely. We then have this series given in the table.

TABLE I.

$a \quad b$
$a+b$
$a+bb$
$a+(bb)(bb)$
$=\ldots ab_4$
$+ab_2 = \ldots\ldots a_2b_6$
$+ab_2 = \ldots\ldots\ldots a_3b_8$
$+ab_2 = \ldots\ldots\ldots a_4b_{10}$
$+ab_2 = \ldots\ldots\ldots a_5b_{12}$
$+ab_2 = \ldots\ldots\ldots\ldots a_6b_{14}$
$+ab_2 = \ldots\ldots\ldots\ldots a_7b_{16}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots a_8b_{18}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots\ldots a_9b_{20}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots\ldots a_{10}b_{22}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots\ldots\ldots a_{11}b_{24}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots\ldots\ldots a_{12}b_{26}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots a_{13}b_{28}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots a_{14}b_{30}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots a_{15}b_{32}$
$+ab_2 = \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots a_{16}b_{34}$

Now, that is an ideal scale. The question is, Is it absurd? How can we honestly answer that question? By asking whether we are or are not on the lines on which nature works in the region of the known, in the region which we can get at?

We will now refer to another diagram; we will pass from the ideal to the concrete, and it will be seen that there is, if one can invert the term in such a way, a distinct precedent for such a table as the last; for here are the absolute facts with regard to one evolutionary series of the combination of carbon and hydrogen. We have the gases CH_4, C_2H_6, C_3H_8; we have as liquids from C_4H_{10} to $C_{15}H_{32}$; each of them formed, not by the addition of my hypothetical ab_2, but by a concrete CH_2, and we have connected with that a beautiful order and exquisite regularity in the way in which the boiling-points and specific gravities of these things increase.

TABLE III.—*Hydrocarbon Series*

			Boiling point.	Specific gravity.
Gaseous	$C\ H_4$	Marsh Gas.		
	$C_2\ H_6$	Ethane.		
	$C_3\ H_8$	Propane.		
Liquid	$C_4\ H_{10}$	Tetrane or Diethyl ...	1° ...	·600 at 0°
	$C_5\ H_{12}$	Pentane	38 ...	·628 at 17
	$C_6\ H_{14}$	Hexane or Dipropyl..	71 ...	·669 at 16
	$C_7\ H_{16}$	Heptane	99 ...	·699 at 15
	$C_8\ H_{18}$	Octane	124 ...	·726 at 15
	$C_9\ H_{20}$	Nonane	148 ...	·728 at 13°5
	$C_{10}H_{22}$	Decane	166 ...	·739 at 13°5
	$C_{11}H_{24}$	Endecane	180 ...	·765 at 16
	$C_{12}H_{26}$	Dodecane or Dihexyl.	202 ...	·774 at 17
	$C_{13}H_{28}$	Tridecane...	218 ...	·792 at 20
	$C_{14}H_{30}$	Tetradecane	230 ...	—
	$C_{15}H_{32}$	Pentadecane	258 ...	·825 at 16
Solid ...	$C_{16}H_{34}$	Hexdecane or Di-octyl	278 Melts at 21°	

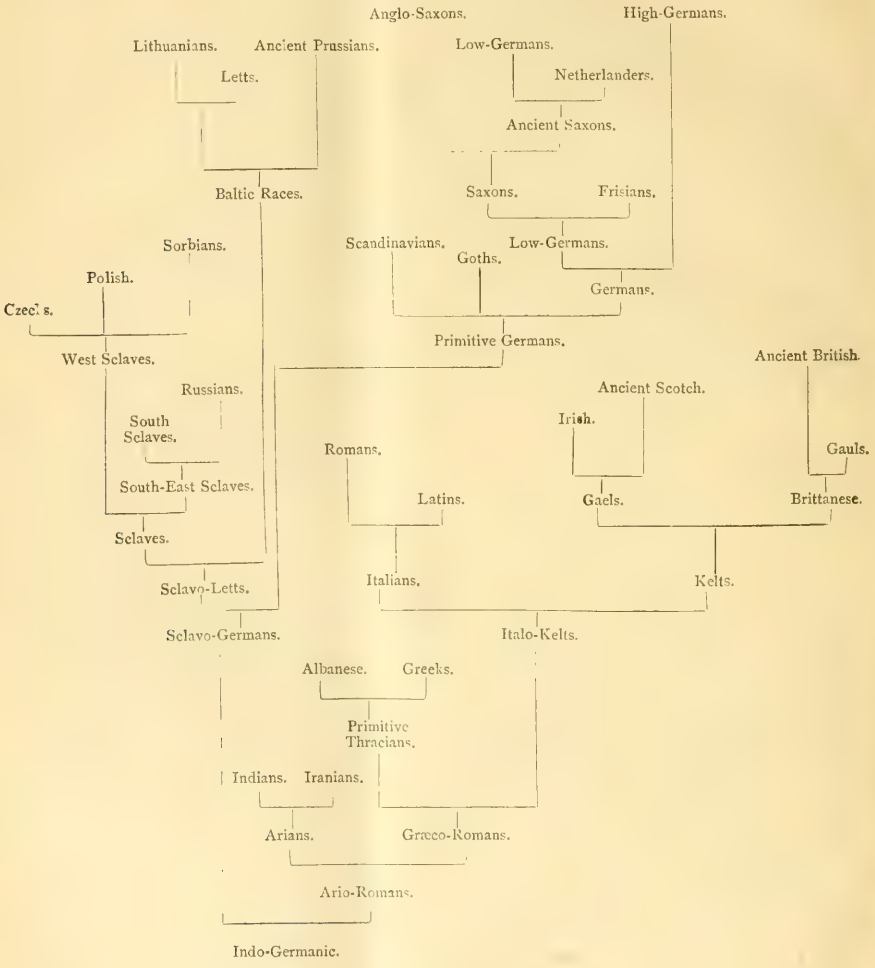
There is no break in the general line of increase, and after we have gone through the gaseous stage, which stops at C_3H_8, and through the liquid stage, which stops at $C_{15}H_{32}$, we get the solid state, and there again the same series is represented. So that I think one is justified in saying that, dealing with this one simple case (and the only reason I have taken the simple case is that it is a line which has been thoroughly worked out by organic chemists), taking this simple case we are justified in saying that if nature, in the regions which we cannot get at, works in the same way as she does in the regions which we can get at, the view is not absurd, and in fact any one who wishes to dispute the view in such a case as this has, I think, the *onus probandi* thrown upon him. He must show that either in a certain latitude or longitude, or at a certain temperature, or under some unknown condition the laws of nature are absolutely changed, and give place to new ones. That has not yet been found in any other region of natural philosophy. Indeed I think one might go further and say that all these evolutionary processes, obtained from different regions of thought, have such a oneness about them that to my mind one of the best mental images we can get of the causes which produce the lines picked out for special prominence in solar spots and solar flames, is to consider the molecular groupings that produce them as resembling the roots of the present European languages which our ancestors brought from the cradle of the race in Asia.

The accompanying diagram (p. 396) is taken from Haeckel's book. We begin with the European languages, including our own, High-German, and so on, and philologists have traced them down into Indo-German. We have at present in our language few and far between, the root-words which have existed almost unchanged from the time when this language only was spoken. There has been an evolution in language as there has been an evolution brought about by the reduction of temperature wherever chemical substances have been allowed to intermingle with each other, but side by side with the new chemical forms produced by the low temperature, and represented by the later languages, remain true root-forms, which may be traced to the hottest regions within our ken in the same way as the root-forms in our own language can be traced through these other forms of language back to the first one with which we are acquainted.

Now comes the second question, to which reference has been made. What is the opinion of those who have given the greatest attention to chemical philosophy? I do not mean to chemistry, I mean to chemical philosophy. We begin with Dalton. He says, "We do not know that any one of the bodies denominated elementary is absolutely indecomposable." I go on to Graham: "It is conceivable that the various kinds of matter now recognised in different elementary substances may possess one

and the same element or atomic molecule existing in different conditions of movability. The essential unity of matter is an hypothesis in harmony with the equal action of gravity upon all bodies." I now come to Sir Benjamin Brodie, whom we have so lately lost, the last of the great English triumvirate to whom I mean to refer. His views I have already stated in his own words, but I may here again state that as early as 1867, almost, we may say, before the spectroscope had been applied to the sun, except in the general way, which was started by Fraunhofer and Kirchhoff, he prophesied that the solar facts would be as I think we have found them. That is to say, he stated his belief that at the solar temperature the constituents of our elementary bodies would be found existing in independent forms. The greatest chemical philosopher now living, M. Dumas, so

PEDIGREE OF THE INDO-GERMANIC LANGUAGES.



long ago as 1836 published a series of lectures in which his views were very clearly stated indeed, and any one who reads them will see how convinced he was then of the considerable amount of evidence that had already been accumulated in favour of the non-elementary nature of a great number of substances then classed as elements.

Then again we can pass to another chemical philosopher, Kopp. In his researches on specific heats he also gives evidence to show that that relationship is not to be depended upon to establish the received view. If, then, the three greatest English chemists we can name, and the most eminent chemical philosophers in France and Germany, give their opinion in behalf of the compound nature of the chemical elements, can these simpler forms be any other than those we detect by means of the spectroscope? By the conditions of the problem and the absence of knowledge they are not decomposable in the laboratory; if they

were they would cease to be elementary bodies at once, and would be wiped out of our tables. Nor do I think it possible that in the present stage of our knowledge they can be revealed to us in any other way than by the spectroscope. It is unfortunate that none of these chemists who have given us this view have helped us by showing in what way the possibility, which all of them suggest, and which many of them intensely believe in, could be absolutely demonstrated, but it is obvious that if dissociation is the thing which time out of mind has made compound bodies simpler, in their minds the condition of higher temperature must have been present. The only difficulty was the way in which the effects of that high temperature could be measured and weighed, and I think that if the spectroscope had been introduced earlier they would probably have left some hints behind them which would have been of the greatest value to those who work with that instrument.

Passing from the chemists to the physicists, there is one, at all events, who has appreciated exactly how this decomposibility of the terrestrial elements could be established. I refer to the lamented Clerk Maxwell. In his article on atoms in the "Encyclopædia Britannica," he says: "The discovery of a particular line in a celestial spectrum which does not coincide with any line in a terrestrial spectrum indicates either that a substance exists in the heavenly body not yet detected by chemistry on earth, or" (and it is to the "or" I wish to draw attention) "that the temperature of the heavenly body is such that some substance undecomposable by our methods is there split up into components unknown to us in their separate states." Absolutely nothing could be clearer than this.

In endeavouring to discuss the bearing of this application of the hypothesis of evolution of chemical forms upon modern chemistry, we must draw a very wide distinction between chemical theory and chemical fact.

When we compare the laws given in average chemical text-books with the laws which lie at the root, let us say, of astronomy, the candid mind cannot fail to be struck by the difficulty which chemists must have encountered in endeavouring to reduce the facts of their science to order on the hypothesis they bring before us. An outsider, for instance, thinks that the basis of chemistry, or a large part of the basis of chemistry at all events, lies in the fact that the chemist has determined the existence of a certain number of elementary bodies, each of these elementary bodies having a certain atomic weight, and that this atomic weight determines all the constants of that body. Yet we read in chemical text-books that this atomic weight is fixed according to no invariable rule; indeed, with Kepler's laws and Newton's laws in one's mind one comes to the conclusion that it is not too much to say that it is determined by a series of compromises. An outsider would think that if any one of these elementary bodies were taken as a standard, the weight of an equal volume of vapour of another substance under equal conditions would bear some relationship of a definite character to the atomic weight. This however is not the case. Again, among the questions to be considered as determining the atomic weights taken, is an assumed limitation of combination power, a so-called atomicity, according to which one substance is a monad, because it will combine with that same relative proportion of hydrogen which exists in half a water-molecule. Another substance is called a dyad, because it will combine with the same relative proportion of hydrogen which exists in a whole water-molecule, and so on. When we thus begin to class the substances into monads, dyads, hexads, and so forth; in fact, when we thus effect a re-classification of elementary bodies, the solidarity at once breaks down; we find that the classification after all is useless, because the same substance may behave as a dyad, a tetrad, a hexad, a pseudo-tryad, a pseudo-octad; in fact, one feels one is dealing with something that is more like a moral than a physical attribute—a sort of expression of free will on the part of the molecules. We are, I think, justified in asking whether these various attempts to formulate a science do not break down after a certain point, because they attempt to give a fixity to what is in truth variable.

When we pass to the *facts* of the science, the key-note of which is variability from one end of the scale to the other, we find that the view of successive dissociations, the view of variable molecular groupings brought about under different conditions, is really more or less in accordance with the facts where the laws based on the fixity of the facts break down entirely. Thus, for instance, let us take the question of vapour densities. The view accounts fully for the so-called anomalous vapour densities, and in this way: it suggests that the elements may really be complex groups which break up into their constituent groups under suitable conditions of temperature, like phosphoric chloride and many other bodies do when obtained in the condition of vapour. We have dissimilar groups in the one case, and possibly similar groups in the other. In this way, that contradiction in terms, the "monatomic molecule," really becomes the evidence of a higher law.

Let us pass to allotropic conditions. The explanation of these is that there are bodies which have a large molecular range within the ordinary temperatures at our command. The substances in which allotropism is most marked are all metalloids which have not been found in the sun, and the allotropic forms give us in many cases different spectra—spectra indicating a considerable complexity of the molecules which produce them—spectra of continuous absorption, continuous radiation in the blue, continuous absorption in the red, fluted spectra, and the like. In the passage from one allotropic condition to the other, energy, without any known exception, is absorbed or given out. What becomes of this energy; what is it doing; unless it is in some way or other controlling the passage from one molecular group to another? These allotropic conditions, occurring very obviously to us in certain limits at our ordinary temperature and pressure are, I hold, but special cases of group-condensation common to all bodies, represented by Dalton's law of multiple proportions. We can indeed imagine a condition of things in which the difference between iron in Fe_6, and the iron in Fe_2Cl_6, would be as obvious as the difference between ordinary and amorphous phosphorus.

In certain classes of so-called organic substances this grouping of simpler groups to more complex actually takes place, and is recognised under the term polymerism—for instance, with cyanogen compounds of oxygen we have a simple thing like CNO say, which will form a series of compounds, and we have its so-called polymers, $C_2N_2O_2$, or $C_3N_3O_3$, which will each form a series of compounds, these groups of simpler nature forming by their combination group individuals with related but not identical properties with the simplest or fundamental group.

In many cases the amount of this condensation may be determined by the vapour densities. In others, again, a dissociation takes place at a certain limit of temperature, a simpler or fundamental group being the resolution product.

The resemblance between these cases of polymerism and especially those elementary bodies which exhibit allotropism, is at least striking.

In the one case, the organic complex bodies, the range of existence is in most cases within our easy attainment; in the so-called elementary stuffs it is less frequently the case. We can certainly convert ordinary phosphorus and sulphur into allotropic and most likely polymeric forms, but we do not know as yet how many atoms more are contained in the polymeric forms of these substances than in their simpler states.

And in other substances this range of condition of formation passes gradually out of our reach, but the phenomena are the same in kind up to the temperature of the sun. And again, when we can obtain the spectra of bodies like amorphous phosphorus we can prophesy that the relative grouping of the atoms of phosphorus in this to the ordinary form will be exhibited.

This brings us to the next point—atomicity. What are the associated phenomena? Lowest melting-point, simplest spectrum, lowest atomicity. Therefore we are justified, I think, in assuming that atomicity may after all be but the measure of the molecular groupings at work. In this way we can associate various atomicities, not with moral phenomena as regards the "*behaviour*" of the same molecule, but with different physical states—different complexities of the same substance. Thus in the same substance the more complex or allotropic the molecular grouping, the higher the atomicity. Hence the substances in which the highest atomiticities appear should, as a rule, be formed and broken up at the lowest temperature. This, I am informed, is really what happens in the majority of cases.

New Analogies between Organic and Inorganic Bodies

I have ventured in these few remarks to touch upon the relations of the new view to modern chemical facts, because I think such a discussion shows us that there are several chemical regions in which the views can be tested from a chemical point of view, although I have, from a set purpose in my lectures, dealt with them absolutely from the physical side. In fact, one such

step of the highest interest has already been taken by my colleague, Capt. Abney. I will read what it is, and the language of Prof. Roscoe, the President of the Chemical Society, is so clear and so admirably put, that it is impossible for any one to improve upon it.[1] Referring to the work which Capt. Abney and Col. Festing have done together, he says: This work "is no less than a distinct physical test of the existence in organic compounds, of the organic radicals, and a means of recognising the chemical structure of an organic compound by means of the spectroscope." This result "is accomplished by photographing the absorption spectra of organic compounds in the infra-red part of the spectrum. In these invisible portions characteristic and distinct absorption lines and bands occur for each organic radical. The ethyl compounds all show one special ethyl band; the methyl compounds a special methyl band; and thus, just as a glance at the luminous portion of the spectrum satisfies us of the presence of calcium, lithium, and rhubidium, so a simple inspection of these infra-red photographs enables us to ascertain the presence of the various organic radicals. This invention is still in its infancy, but one of greater importance to chemists has seldom if ever been communicated to the Society." I have been the more anxious to give these results in Prof. Roscoe's own words, because it will be seen that, *mutatis mutandis*, these remarks touching the spectra of organic radicals are precisely the statement I have been endeavouring to make with regard to inorganic radicals. It cannot therefore be said that the nature of the principle I bring forward is one with which chemists are not familiar. In this beautiful work, then, we have an analogy between the behaviour of known compounds and assumed elementary bodies.

A new method of laboratory work which I have recently started may, I think, in the course of time furnish us with another analogy, and in connection with it there is an experiment to which reference may advantageously be made, because it will show what kind of results we expect to get. It is simply referred to as an indication of the probable fruit which will come from many new kinds of experimentation which might be adopted, provided always we bear in view the idea which it has been my duty to bring forward. This experiment is founded on

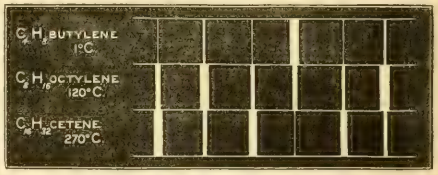


FIG. 47.—Hypothetical spectra obtained on distilling at successively increasing temperatures a mixture of light and heavy hydrocarbons.

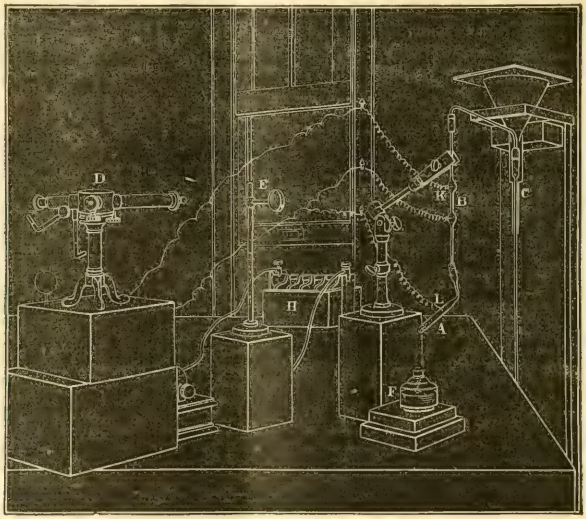

FIG. 48.—Fractional distillation of potassium. A, hard glass tube containing the potassium and connected with a Sprengel pump C by a tube B, having two bulbs with platinum electrodes sealed into them, between which an induced current may be made to pass; F, spirit lamp; H, battery; D, spectroscope; E, lens to focus image of spark on slit of spectroscope.

the behaviour of compound bodies when they are distilled at different temperatures. If we take, for instance, a mixture of hydrocarbons, some of them very complex in their nature, and others more simple; when a low temperature is employed it is found that the simpler hydrocarbon comes over in the shape of vapour. If therefore we were fortunate enough to be able to observe the spectra of these different vapours, assume that that series of hydrocarbons, for instance, shown in the accompanying diagram (Fig. 47), had each of them a distinct spectrum, we should be able to follow spectroscopically the effect of each change of temperature, and we could in that way associate the known fact of the greatest density of the vapour which comes over at a higher temperature with a spectrum of a certain kind.

[1] *Journal* of the Chemical Society, May, 1881.

Now in our experiment we deal not with a compound body in the ordinary sense, but with the so-called elementary body, potassium, which we have in a hard glass tube of the form shown in Fig. 48. By means of a Sprengel pump the tube is very perfectly exhausted, and then gently warmed with a spirit lamp, the exhaustion going on during the whole process. On passing a current between the platinum electrodes we see a beautiful green glow in the tube, and obtain a certain spectrum. On replacing the spirit-lamp by a Bunsen burner we find as the result of this increased temperature that the colour in the tube is blood-red, and the resulting spectrum is entirely different. The spectrum of potassium is one which requires a very great deal of study, for the reason that it varies very much under different experimental conditions. If the

potassium, for instance, is thrown into a Bunsen burner, the chief line that one gets is a red one. Kirchhoff, in the early days of solar chemical investigation, pointed out that this red line is not to be found among the Fraunhofer lines. The flame also gives us a line in the blue. If we examine the spectrum of potassium by means of an induction-coil we find the blue line which we also see in the flame, but it is intensified in the spark. We also see some strong lines in the green and yellow, which are barely visible in the flame—which are in fact not generally recorded in the flame-spectrum of potassium, although they are really visible when considerable dispersion is employed. These lines in the yellow and green I say become prominent lines. Now, it so happens that some of these lines in the green do, it is believed, correspond with Fraunhofer lines, and we are, therefore, justified in assuming that they represent a something, whatever it may be, in the potassium, which can withstand the heat of the sun, while the red lines represent something which

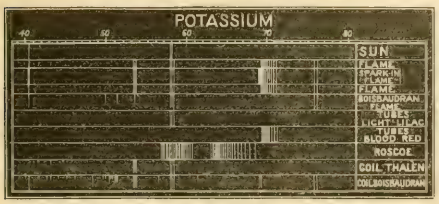

FIG. 49.—Spectra of potassium obtained under different conditions.

is broken up at the temperature of those regions of which we can determine the absorption. The interesting point of the experiment, therefore, is this: assuming for a moment that the red line does represent a complex something which cannot withstand the temperature of the sun, and that the yellow line represents a something finer which can withstand the temperature of the sun, what happens when we try to drive off the vapour of this potassium *at the lowest temperature* at which we can get it to volatilise at all, is that if the experiment is carefully performed it gives precisely those lines which are reversed in the solar spectrum alone, and of that line, which is the strongest line at the temperature of the Bunsen burner we see absolutely nothing at all. Referring to the spectrum which we get in the lilac and yellow-green part of the tube, two out of the three lines visible at all events are seen in the sun, whereas the other lines which we get in the flame and some of them which we get in the coil are not represented in that fine vapour which was produced at the lowest possible temperature.

The Bunsen burner produces some very exquisite colour-effects in the tube, and especially develops a beautiful blood-red colour which might be imagined to be the product of that molecule which gives the red line in the Bunsen burner; but that is not the fact. The line seen in the Bunsen burner is not visible as a rule in the vapour when heated in this way, the lines actually seen being more refrangible. Fig. 49 is a map of the spectrum of potassium under these various conditions. I give it simply as an indication that it is possible when other laboratory and chemical experiments are made with this view in mind that other analogies than those already obtained will be forthcoming.

The experiment then comes to this. If we assume the potassium to be a compound body and that its finer constituent molecules are those which resist the solar temperature, then it behaves exactly like a mixture of hydrocarbons is known to do, that is, the finer vapours come off in greatest quantity at the lowest temperature, and the more complex ones as the temperature is raised.

Conclusion

In concluding my lectures in this course on Solar Physics I would ask attention to the fact that the views which I have ventured to put forward, as being what I honestly believe to be the true outcome of the twenty years' work which has been applied to this subject, depend for their strength upon the convergence of very various lines of thought and work. No doubt the future progress of science will show that we, after all, are looking through a glass darkly, and that we are not yet face to face with the truth, and the whole truth. We must all of us be content to have our work criticised and expanded by future work, by researches carried on with greater skill, with more elaborate methods and higher views. But with all these reservations I do wish to draw attention to the fact that the convergence of many lines of work and many lines of thought suggest the ideas which I have put forward. Depend upon it, that we shall get a much higher and much richer truth out of further inquiries; and I quite acknowledge, although I have had a hand in the work myself, that the outcome of the work is so important that it ought to be considered honestly and carefully from every point of view. Still I consider that I am in honour bound to say, as the result of the work on solar physics, in that small branch of the inquiry into solar matters with which I am more personally connected, that my belief is that the late work has changed the views which were held say twenty years ago to this extent: whereas twenty years ago we imagined ourselves to be in full presence in the sun of chemical forms with which we are familiar here, I think in this present year we are bound to consider that that view may be modified to a certain extent, and that we are justified in holding the view that, not these chemical forms, with which we are acquainted here, but their germs really, are revealed to us in the hottest regions of the sun. J. NORMAN LOCKYER

NOTES FROM THE MALAY ARCHIPELAGO

A CORRESPONDENT in Java sends us the following:—

In 1879 I saw, at Tabu Breio, Padang Panjang, west coast of Sumatra, a child aged about one and a half years, with four legs. It was a female child with perfect organs, only the feet were clubbed and the legs bent. The added-on pair of legs were less perfect and their circulation evidently not in order, for they were not so sensitive to pain (pinches, &c.). They looked as if part of an embryo male child. The child was subject to fits; it could not walk, but crawled, using its female legs, the male (?) legs being dragged along. The spine was much dragged out of position.

During about six months of 1880 there was a child at Surabaya, Java, with two distinct heads joined to one neck. It is now with the Regent (a Javanese) of Surabaya, in spirits. Photographs of this are sold. The brains were quite independent of each other, for the one would sleep whilst the other was awake. I have not heard whether the one could articulate whilst the other slept.

Bornean Rhinoceros.—Mr. Bartlett writes to me: "We now know for certain that the Bornean is the same as the Sumatran. This comes of course from Hart Everett, and I do not doubt it for a moment." But I have strong grounds for believing that there are two kinds:—1. A Government official who recently spent a year in the deepest recesses of the island says the natives told him there were two kinds. 2. About eight years ago a small rhinoceros was killed at Bunut, about 150 miles above Sintang, on the Pontianak. This is certain, it had only one horn. I have recently spoken to an officer who spent a year and a half in the interior, and he says he always understood the animal had only one horn. Anyhow it is very rare indeed. No European I have met—and many have been a long way into Borneo—has seen it. That may be because they are phlegmatic Dutch, and not inquiring English. But the natives who killed the one at Bunut had never seen one before. At the first sight they fled in terror at such a beast. It might have been a young *R. Sum.*, as the horn was very small, and perhaps the trifling development of bud horn escaped notice.

A Dutch ship, the *Batavia*, has at length reached the point where the 141st degree cuts the west coast of New Guinea. This is considered a great feat; why, I can't precisely say. There has been a good deal of talk about sending explorers to the Dutch end of New Guinea, but directly money is asked for silence reigns. They had much better finish with Sumatra before going to New Guinea.

The cattle plague has been raging in the west end of Java, Bantam, the Preanger, and Batavia residences—during the west monsoon (now finishing) with redoubled vigour. It has now abated a little (after four years it may well do so, from want of victims) in these parts, but is extending eastward, its appearance in Krawang being the most alarming. The authorities have decided upon making a double fence right across Java at its narrowest part. This means a line from somewhere about Cheribon due south. In the interval—a considerable one—

between the two fences, no cattle will be allowed to pass or exist.

There is a bird (native name Jallak) which follows the buffaloes about and perches on their backs. Query, can this bird have anything to do with the spreading of the plague? If so I don't see what Government can do. They can't fence him out.

In all the parts where the cattle-plague has raged the most awful fevers have been the result amongst the native population. In Bantam alone 50,000 died in 1880. In the Preanger and Batavia the death-rate was also very high. There is no doubt whatever that this is due to the imperfect interment of the carcases. The Government says it is due to the wet season; but this is a lame excuse, for why is there no fever elsewhere? In the wet season it is, of course, worse, for the heavy rains cause more miasma.

THURSDAY, SEPTEMBER 1, 1881

THE BRITISH ASSOCIATION

THE Fifty-first Annual Meeting of the British Association was opened yesterday under the presidency of Sir John Lubbock, Bart., M.P., F.R.S., at York, the birthplace of the Association fifty years ago (September 27, 1831). Almost as easily might we compare the first meeting of the Accademia del Cimento when Roberval and Mersennus and Torricelli discussed the nature of the vacuum with the last meeting of the Nuovo Cimento, as compare the meeting of the British Association of 1831 with that of 1881. Railways, telegraphs, telephones, and electric lighting were unknown; the doctrines of evolution and the conservation of energy had not been developed; geology, palæontology, and petrology were in their infancy; the modern applications of spectroscopy were scarcely thought of; the mechanical equivalent of heat had not been determined. Several sciences, which at that time consisted of a mere collection of ill-arranged facts, have since, by the application of logical methods, had conferred upon them an individuality which they never before possessed. Science schools have arisen in all directions; the State yearly examines some thousands of its subjects; the Universities have created new professorships, have vitalised the old ones, and have placed science scholarships on an equality with those which formerly were only given for classics and mathematics. The Universities having opened their doors to the new culture, and it has become a necessary part of elementary education; while technical schools in all our large centres instruct thousands of artisans in the rudiments of natural knowledge. Has the British Association kept pace with this prodigious development?

What were the ideas of its founders? William Vernon Harcourt, "the lawgiver and proper founder of the British Association," said at the opening meeting that its objects should be "to give a stronger impulse and more systematic direction to scientific inquiry, to obtain a greater degree of national attention to the objects of science, and a removal of those disadvantages which impede its progress, and to promote the intercourse of the cultivators of science with one another and with foreign philosophers." By its reports, committees, recommendations, and grants, the Association has to some extent succeeded in each of these objects. But Mr. Vernon Harcourt planned the Association on a wider basis than that upon which it rests. "I propose to you," he said, "to found an association, including all the strength of Great Britain, which shall employ a short period of every year in pointing out the lines of direction in which the researches of science should move; in indicating the particulars which most immediately demand investigation; in stating problems to be solved and data to be fixed; in assigning to every class of mind a definite task; and suggesting to its members that there is here a shore of which the soundings should be more accurately taken, and there a line of coast along which a voyage of discovery should be made." We venture to think that this course of action might be more closely followed with advantage. It is true that a few committees are appointed to report upon, and sometimes to experiment upon, certain defined objects, but if each section could give a list of the most important questions awaiting answer in its particular science—somewhat in the form of a modernised *Inquisitio de Naturâ Calidi*—energy would less often be expended about the mint, the anise, and the cumin, and more often applied to the weightier matters of the sciences. Men would then more frequently forge connections in the mighty chain, in place of separate links which sometimes rust away before a place is found for them.

The earlier presidents delighted to find in the Association the development of Bacon's idea of the "New Atlantis." But we venture with great deference to submit that it never has and never can approach the character of that academy of universal science. A nearer approach to it was to be found in the old Gresham College, and may now be met with in any one of the new colleges of sciences. Bacon's idea was to have a vast inclosure containing "elaboratories chymicall and phisicall," anatomical and metallurgical, observatories of every kind, botanical gardens, museums, and operatories for every science. Connected with these there was to be a staff of workers and a staff of thinkers; also a kind of scientific society, or collection of societies, in which the results should be discussed. There are a thousand workers in the domains of the sciences now where there was one fifty years ago; discoveries and inventions multiply, and scientific literature is assuming vast proportions; but at present we are as far from the lofty and majestic ideal of the New Atlantis as we were in 1831.

But let us not for a moment underrate the valuable work which the Association has accomplished. Many of the Reports of committees or individuals are classical, and the suggestions which they furnish have led to considerable results. Take one example: the establishment of magnetic observatories all over the world is mainly due to the action of the Association. "By no sudden impulse or accidental circumstance," said Prof. Phillips in the Birmingham presidential address in 1865, "rose to its high importance that great system of magnetic observations on which for more than a quarter of a century the British Association and the Royal Society, acting in concert, have been intent. First we had reports on the mathematical theory, and experimental researches of magnetism by Christie, 1833; Whewell, 1835; and Sabine, 1835. Afterwards a magnetic survey of the British Islands; then the establishment of a complete observatory at Dublin, with newly arranged instruments, by Dr. Lloyd in 1838. On all this gathered experience we founded a memorial to Her Majesty's Government, made a grant of 400*l.* from our funds for preliminary expenses, and presented to the meeting of this Association in Birmingham in 1839 a report of progress signed by Herschel and Lloyd. From that time how great the labour, how inestimable the fruits! Ross sails to the magnetic pole of the south; America and Russia co-operate with our observers at Kew, Toronto, and St. Helena; and General Sabine, by combining all this united labour, has the happiness of seeing results established of which no man dreamed—laws of harmonious variation affecting the magnetic elements of the globe, indefinite relation to the earth's

movement, the position of the sun and moon, the distribution of temperature, and the situation in latitude and longitude."

We must bear in mind, however, that the great mass of members at any one meeting are not made up of scientific men who can appreciate the full development of a train of ideas or results, but of people who have not the advantages of attending the meetings of the London scientific societies, or of being *au courant* with scientific progress, and we may fitly inquire by what means their interests are best served. The President's address is perhaps the most powerful stimulus. Such addresses usually belong to one of three classes :—they are either distinguished by a fine display of oratory ; or by the discussion of some leading theory concerning which the president has a right to speak *ex cathedrâ;* or they give a *résumé* of the scientific progress of the year. This last is of the greatest utility to the general run of members. Sometimes the three classes are judiciously combined, and these addresses are commonly the best of all. In former years the Presidential Address was very short, and chiefly discussed the results obtained by the Committees, and the Reports thereon. Occasionally an unscientific nobleman has opened the proceedings by a *quasi* after-dinner speech, while anon we have a sophistical declamation dealing with some of the burning questions of the hour, and disposing of them bravely.

Many cities have received the Association twice, but few three times. York will now be one of the latter, but it is thirty-six years since the last meeting was held there. Murchison called it the "cradle of the Association," and at the second York meeting the tickets bore the inscription, *Antiquam exquirite Matrem.* If the Association carries out the ideas of its founders, we may fairly hope that a centennial and even a millennial meeting will be held in the place of its birth. The city has many objects of interest : it possesses convenient accommodation for all the sections, and a number of important manufactories can be easily visited from it. The local committee have issued an extremely useful programme of their arrangements, which not only contains all the necessary information concerning trains, posts, lodgings, and the places of meeting, but also articles on the zoology, botany, and geology of the neighbourhood, and a description of the various excursions. An interesting article on "The York Founders of the Association" is contributed by Archdeacon Hey. An exhibition of art and industrial produce, and a collection of scientific apparatus, will be open during the week. Four excursions are organised for Saturday, September 3 : to Scarborough ; to Castle Howard ; to Helmsley and Rievaulx ; and to Brimham Rocks and Harrogate. On the following Thursday there will be seven excursions : to Bolton Abbey and the Strid ; to Cleveland ; a coast excursion ; to Gristhorpe, Speeton, and Scarborough ; to Whitby ; to Wensleydale ; and to Aldborough and Boroughbridge. Among the more important manufactories which will be visited are the telescope works of Messrs. Cooke and Sons, the workshops of the North Eastern Railway, the York glass works, and some extensive confectionery works. Naturalists will be glad to learn that the county possesses a fauna which comprises 513 out of the 717 British Vertebrata, viz. 46 mammals, 307 birds, 12 reptiles, and 148 fishes. It also furnishes 71 per cent. of the British flowering-plants and ferns. Geologically the county consists of rounded Chalk Hills, Oolite overlying the Lias, Trias covered with glacial drift and alluvial deposit, and a narrow band of Permian strata. Many opportunities will be afforded to members of studying the geology of the district.

The famous Kirkdale Cave, which was the first to be scientifically examined, gave rise to the Yorkshire Philosophical Society. The numerous remains found in it became the basis of a museum, and to it was attached the scientific society of which John Phillips was one of the secretaries. The idea of the Association was broached by Brewster in a letter to Phillips. The Council of the Yorkshire Society issued the first invitations, and its president, vice-president, treasurer, and secretaries filled the same offices at the first meeting of the Association. The writer of an able article in the *Times* of last Friday points out that in place of the few philosophical societies of fifty years ago there are now a hundred or two scattered all over the country often doing good work, which is to a great extent lost or wasted because inaccessible to the scientific world, and he suggests that the Association should act as a bond of union between these societies, proposing methods of work and special kinds of research suitable to the particular district. This might surely be done with great advantage in the case of the natural history sciences and geology ; and we think the idea is worthy the attention of the Association. If, furthermore, it could publish a *résumé* of the more important results obtained by the several local societies during each year, it would be a boon to scientific literature.

As might have been expected, the "Jubilee Meeting" of the Association is likely to attract an unusually large gathering. On Tuesday upwards of 1500 names had been enrolled. The special character of the meeting is likely to have an influence not only on the presidential addresses, but on the nature of the entire proceedings.

Inaugural Address by Sir John Lubbock, Bart., M.P., F.R.S., D.C.L., LL.D., President

In the name of the British Association, which for the time I very unworthily represent, I beg to tender to you, my Lord Mayor, and through you to the City of York, our cordial thanks for your hospitable invitation and hearty welcome.

We feel, indeed, that in coming to York we are coming home : gratefully as we acknowledge and much as we appreciate the kindness we have experienced elsewhere, and the friendly relations which exist between this Association and most—I might even say, all—our great cities, yet Sir R. Murchison truly observed at the close of our first meeting in 1831, that to York, "as the cradle of the Association, we shall ever look back with gratitude ; and whether we meet hereafter on the banks of the Isis, the Cam, or the Forth, to this spot we shall still fondly revert." Indeed, it would have been a matter of much regret to all of us, if we had not been able on this, our fiftieth anniversary, to hold our meeting in our mother city.

My Lord Mayor, before going further, I must express my regret, especially when I call to mind the illustrious men who have preceded me in this chair, that it has not fallen to one of my eminent friends around me, to preside on this auspicious occasion. Conscious, however, as I am of my own deficiencies, I feel that I must not waste time in dwelling on them, more especially as in doing so I should but give them greater prominence. I will, therefore, only make one earnest appeal to your kind indulgence.

The connection of the British Association with the City of York does not depend merely on the fact that our first meeting was held here. It originated in a letter addressed by Sir D. Brewster to Prof. Phillips, as Secretary to your York Philosophical Society, by whom the idea was warmly taken up. The first meeting was held on September 26, 1831, the chair being taken by Lord Milton, who delivered an address, after which Mr. William Vernon Harcourt, Chairman of the Committee of Management, submitted to the meeting a code of rules which had been so maturely considered, and so wisely framed, that they have remained substantially the same down to the present day.

The constitution and objects of the Association were so ably described by Mr. Spottiswoode, at Dublin, and are so well known to you, that I will not dwell on them this evening. The excellent President of the Royal Society, in the same address, suggested that the past history of the Association would form an appropriate theme for the present meeting. The history of the Association, however, is really the history of science, and I long shrank from the attempt to give even a panoramic survey of a subject so vast and so difficult ; nor should I have ventured to make any such attempt, but that I knew I could

rely on the assistance of friends in every department of science.

Certainly, however, this is an opportunity on which it may be well for us to consider what have been the principal scientific results of the last half-century, dwelling especially on those with which this Association is more directly concerned, either as being the work of our own members, or as having been made known at our meetings. It is of course impossible within the limits of a single address to do more than allude to a few of these, and that very briefly. In dealing with so large a subject I first hoped that I might take our annual volumes as a text-book. This, however, I at once found to be quite impossible. For instance, the first volume commences with a Report on Astronomy by Sir G. Airy; I may be pardoned, I trust, for expressing my pleasure at finding that the second was one by my father, on the Tides, prepared like the preceding at the request of the Council; then comes one on Meteorology by Forbes, Radiant Heat by Baden Powell, Optics by Brewster, Mineralogy by Whewell, and so on. My best course will therefore be to take our different Sections one by one, and endeavour to bring before you a few of the principal results which have been obtained in each department.

The Biological Section is that with which I have been most intimately associated, and with which it is, perhaps, natural that I should begin.

Fifty years ago it was the general opinion that animals and plants came into existence just as we now see them. We took pleasure in their beauty; their adaptation to their habits and mode of life in many cases could not be overlooked or misunderstood. Nevertheless, the book of Nature was like some richly illuminated missal, written in an unknown tongue; the graceful forms of the letters, the beauty of the colouring, excited our wonder and admiration; but of the true meaning little was known to us; indeed we scarcely realised that there was any meaning to decipher. Now glimpses of the truth are gradually revealing themselves; we perceive that there is a reason—and in many cases we know what that reason is—for every difference in form, in size, and in colour; for every bone and every feather, almost for every hair. Moreover, each problem which is solved opens out vistas, as it were, of others perhaps even more interesting. With this great change the name of our illustrious countryman, Darwin, is intimately associated, and the year 1859 will always be memorable in science as having produced his great work on "The Origin of Species." In the previous year he and Wallace had published short papers, in which they clearly state the theory of natural selection, at which they had simultaneously and independently arrived. We cannot wonder that Darwin's views should have at first excited great opposition. Nevertheless from the first they met with powerful support, especially, in this country, from Hooker, Huxley, and Herbert Spencer. The theory is based on four axioms:—

"1. That no two animals or plants in nature are identical in all respects.

"2. That the offspring tend to inherit the peculiarities of their parents.

"3. That of those which come into existence, only a small number reach maturity.

"4. That those, which are, on the whole, best adapted to the circumstances in which they are placed, are most likely to leave descendants."

Darwin commenced his work by discussing the causes and extent of variability in animals, and the origin of domestic varieties; he showed the impossibility of distinguishing between varieties and species, and pointed out the wide differences which man has produced in some cases—as, for instance, in our domestic pigeons, all unquestionably descended from a common stock. He dwelt on the struggle for existence (which has since become a household word), and which, inevitably resulting in the survival of the fittest, tends gradually to adapt any race of animals to the conditions in which it occurs.

While thus, however, showing the great importance of natural selection, he attributed to it no exclusive influence, but fully admitted that other causes—the use and disuse of organs, sexual selection, &c.—had to be taken into consideration. Passing on to the difficulties of his theory he accounted for the absence of intermediate varieties between species, to a great extent, by the imperfection of the geological record.

But if the geological record be imperfect, it is still very instructive. The further palæontology has progressed the more it has tended to fill up the gaps between existing groups and species, while the careful study of living forms has brought into prominence the variations dependent on food, climate, habitat, and other conditions, and shown that many species long supposed to be absolutely distinct are so closely linked together by intermediate forms that it is difficult to draw a satisfactory line between them.

The principles of classification point also in the same direction, and are based more and more on the theory of descent. Biologists endeavour to arrange animals on what is called the "natural system." No one now places whales among fish, bats among birds, or shrews with mice, notwithstanding their external similarity; and Darwin maintained that "community of descent was the hidden bond which naturalists had been unconsciously seeking." How else, indeed, can we explain the fact that the framework of bones is so similar in the arm of a man, the wing of a bat, the fore-leg of a horse, and the fin of a porpoise—that the neck of a giraffe and that of an elephant contain the same number of vertebræ?

Strong evidence is, moreover, afforded by embryology; by the presence of rudimentary organs and transient characters, as, for instance, the existence in the calf of certain teeth which never cut the gums, the shrivelled and useless wings of some beetles, the presence of a series of arteries in the embryos of the higher Vertebrata exactly similar to those which supply the gills in fishes, even the spots on the young blackbird, the stripes on the lion's cub; these, and innumerable other facts of the same character, appear to be incompatible with the idea that each species was specially and independently created; and to prove, on the contrary, that the embryonic stages of species show us more or less clearly the structure of their ancestors.

Darwin's views, however, are still much misunderstood. I believe there are thousands who consider that according to his theory a sheep might turn into a cow, or a zebra into a horse. No one would more confidently withstand any such hypothesis, his view being, of course, not that the one could be changed into the other, but that both are descended from a common ancestor.

No one, at any rate, will question the immense impulse which Darwin has given to the study of natural history, the number of new views he has opened up, and the additional interest which he has aroused in, and contributed to, Biology. When we were young we knew that the leopard had spots, the tiger was striped, and the lion tawny; but why this was so it did not occur to us to ask; and if we had asked no one would have answered. Now we see at a glance that the stripes of the tiger have reference to its life among jungle-grasses; the lion is sandy, like the desert; while the markings of the leopard resemble spots of sunshine glancing through the leaves.

The science of embryology may almost be said to have been created in the last half-century. Fifty years ago it was a very general opinion that animals which are unlike when mature, were dissimilar from the beginning. It is to Von Baer, the discoverer of the mammalian ovum, that we owe the great generalisation that the development of the egg is in the main a progress from the general to the special, in fact, that embryology is the key to the laws of animal development.

Thus the young of existing species resemble in many cases the mature forms which flourished in ancient times. Huxley has traced up the genealogy of the horse to the Miocene Anchitherium. In the same way Gaudry has called attention to the fact that just as the individual stag gradually acquires more and more complex antlers: having at first only a single prong, in the next year two points, in the following three, and so on; so the genus, as a whole, in Middle Miocene times, had two pronged horns; in the Upper Miocene, three; and that it is not till the Upper Pliocene that we find any species with the magnificent antlers of our modern deer. It seems to be now generally admitted that birds have come down to us through the Dinosaurians, and, as Huxley has shown, the profound break once supposed to exist between birds and reptiles has been bridged over by the discovery of reptilian birds and bird-like reptiles; so that, in fact, birds are modified reptiles. Again, the remarkable genus Peripatus, so well studied by Moseley, tends to connect the annulose and articulate types.

Again, the structural resemblances between Amphioxus and the Ascidians had been pointed out by Goodsir; and Kowalevsky in 1866 showed that these were not mere analogies, but indicated a real affinity. These observations, in the words of Allen Thomson, "have produced a change little short of revolutionary in embryological and zoological views, leading as they do to

the support of the hypothesis that the Ascidian is an earlier stage in the phylogenetic history of the mammal and other vertebrates."

The larval forms which occur in so many groups, and of which the Insects afford us the most familiar examples, are, in the words of Quatrefages, embryos, which lead an independent life. In such cases as these external conditions act upon the larvæ as they do upon the mature form; hence we have two classes of changes, adaptational or adaptive, and developmental. These and many other facts must be taken into consideration; nevertheless naturalists are now generally agreed that embryological characters are of high value as guides in classification, and it may, I think, be regarded as well-established that, just as the contents and sequence of rocks teach us the past history of the earth, so is the gradual development of the species indicated by the structure of the embryo and its developmental changes.

When the supporters of Darwin are told that his theory is incredible, they may fairly ask why it is impossible that a species in the course of hundreds of thousands of years should have passed through changes which occupy only a few days or weeks in the life-history of each individual?

The phenomena of yolk-segmentation, first observed by Prevost and Dumas, are now known to be in some form or other invariably the precursors of embryonic development; while they reproduce, as the first stages in the formation of the higher animals, the main and essential features in the life-history of the lowest forms. The "blastoderm" as it is called, or first germ of the embryo in the egg, divides itself into two layers, corresponding, as Huxley has shown, to the two layers into which the body of the Cœlenterata may be divided. Not only so, but most embryos at an early stage of development have the form of a cup, the walls of which are formed by the two layers of the blastoderm. Kowalevsky was the first to show the prevalence of this embryonic form, and subsequently Lankester and Hæckel put forward the hypothesis that it was the embryonic repetition of an ancestral type, from which all the higher forms are descended. The cavity of the cup is supposed to be the stomach of this simple organism, and the opening of the cup the mouth. The inner layer of the wall of the cup constitutes the digestive membrane, and the outer the skin. To this form Hæckel gave the name Gastræa. It is perhaps doubtful whether the theory of Lankester and Hæckel can be accepted in precisely the form they propounded it; but it has had an important influence on the progress of embryology. I cannot quit the science of embryology without alluding to the very admirable work on "Comparative Embryology" by our new general secretary, Mr. Balfour, and also the "Elements of Embryology" which he had previously published in conjunction with Dr. M. Foster.

In 1842, Steenstrup published his celebrated work on the "Alternation of Generations," in which he showed that many species are represented by two perfectly distinct types or broods, differing in form, structure, and habits; that in one of them males are entirely wanting, and that the reproduction is effected by fission, or by buds, which, however, are in some cases structurally indistinguishable from eggs. Steenstrup's illustrations were mainly taken from marine or parasitic species, of very great interest, but not generally familiar, excepting to naturalists. It has since been shown that the common Cynips or Gallfly is also a case in point. It had long been known that in some genera belonging to this group, males are entirely wanting, and it has now been shown by Bassett, and more thoroughly by Adler, that some of these species are double-brooded; the two broods having been considered as distinct genera.

Thus an insect known as *Neuroterus lenticularis*, of which females only occur, produces the familiar oak-spangles so common on the under sides of oak leaves, from which emerge, not *Neuroterus lenticularis*, but an insect hitherto considered as a distinct species, belonging even to a different genus, *Spathegaster baccarum*. In Spathegaster both sexes occur; they produce the currant-like galls found on oaks, and from these galls Neuroterus is again developed. So also the King Charles oak-apples produce a species known as *Teras terminalis*, which descends to the ground, and makes small galls on the roots of the oak. From these emerge an insect known as *Biorhiza aptera*, which again gives rise to the common oak-apple.

It might seem that such inquiries as these could hardly have any practical bearing. Yet it is not improbable that they may lead to very important results. For instance, it would appear that the fluke which produces the rot in sheep, passes one phase of its existence in the black slug, and we are not without hopes that the researches, in which our lamented friend Prof. Rolleston was engaged at the time of his death, which we all so much deplore, will lead, if not to the extirpation, at any rate to the diminution, of a pest from which our farmers have so grievously suffered.

It was in the year 1839 that Schwann and Schleiden demonstrated the intimate relation in which animals and plants stand to each other, by showing the identity of the laws of development of the elementary parts in the two kingdoms of organic nature.

As regards descriptive biology, by far the greater number of species now recorded have beeen named and described within the last half-century.

Dr. Günther has been good enough to make a calculation for me. The numbers, of course, are only approximate, but it appears that while the total number of animals described up to 1831 was not more than 70,000, the number now is at least 320,000.

Lastly, to show how large a field still remains for exploration, I may add that Mr. Waterhouse estimates that the British Museum alone contains not fewer than 12,000 species of insects which have not yet been described, while our collections do not probably contain anything like one-half of those actually in existence. Further than this, the anatomy and habits even of those which have been described offer an inexhaustible field for research, and it is not going too far to say that there is not a single species which would not amply repay the devotion of a lifetime.

One remarkable feature in the modern progress of biological science has been the application of improved methods of observation and experiment; and the employment in physiological research of the exact measurements employed by the experimental physicist. Our microscopes have been greatly improved. The use of chemical re-agents in microscopical investigations has proved most instructive, and another very important method of investigation has been the power of obtaining very thin slices by imbedding the object to be examined in paraffin or some other soft substance. In this manner we can now obtain, say, fifty separate sections of the egg of a beetle, or the brain of a bee.

At the close of the last century, Sprengel published a most suggestive work on flowers, in which he pointed out the curious relation existing between these and insects, and showed that the latter carry the pollen from flower to flower. His observations, however, attracted little notice until Darwin called attention to the subject in 1862. It had long been known that the cowslip and primrose exist under two forms, about equally numerous, and differing from one another in the arrangements of their stamens and pistils; the one form having the stamens on the summit of the flower and the stigma half-way down; while in the other the relative positions are reversed, the stigma being at the summit of the tube and the stamens half-way down. This difference had, however, been regarded as a case of mere variability; but Darwin showed it to be a beautiful provision, the result of which is that insects fertilise each flower with pollen brought from a different plant; and he proved that flowers fertilised with pollen from the other form yield more seed than if fertilised with pollen of the same form, even if taken from a different plant.

Attention having been thus directed to the question, an astonishing variety of most beautiful contrivances have been observed and described by many botanists, especially Hooker, Axel, Delpino, Hildebrand, Bennett, Fritz Müller, and above all Hermann Müller and Darwin himself. The general result is that to insects, and especially to bees, we owe the beauty of our gardens, the sweetness of our fields. To their beneficent, though unconscious action, flowers owe their scent and colour, their honey—nay, in many cases, even their form. Their present shape and varied arrangements, their brilliant colours, their honey, and their sweet scent are all due to the selection exercised by insects.

In these cases the relation between plants and insects is one of mutual advantage. In many species, however, plants present us with complex arrangements adapted to protect them from insects; such, for instance, are in many cases the resinous glands which render leaves unpalatable; the thickets of hairs and other precautions which prevent flowers from being robbed of their honey by ants. Again, more than a century ago, our countryman, Ellis, described an American plant, Dionæa, in which the leaves are somewhat concave, with long lateral spines and a joint in the middle; close up with a jerk, like a rat-trap, the moment any

unwary insect alights on them. The plant, in fact, actually captures and devours insects. This observation also remained as an isolated fact until within the last few years, when Darwin, Hooker, and others have shown that many other species have curious and very varied contrivances for supplying themselves with animal food.

Some of the most fascinating branches of botany—morphology, histology, and physiology—scarcely existed before 1830. In the two former branches the discoveries of von Mohl are pre-eminent. He first observed cell-division in 1835, and detected the presence of starch in chlorophyll-corpuscles in 1837, while he first described protoplasm, now so familiar to us, at least by name, in 1846. In the same year Amici discovered the existence of the embryonic vesicle in the embryo sac, which develops into the embryo when fertilised by the entrance of the pollen-tube into the micropyle. The existence of sexual reproduction in the lower plants was doubtful, or at least doubted by some eminent authorities, as recently as 1853, when the actual process of fertilisation in the common bladderwrack of our shores was observed by Thuret, while the reproduction of the larger fungi was first worked out by De Bary in 1863.

As regards lichens, Schwendener proposed, in 1869, the startling theory, now however accepted by some of the highest authorities, that lichens are not autonomous organisms, but commensal associations of a fungus parasitic on an alga. With reference to the higher Cryptogams it is hardly too much to say that the whole of our exact knowledge of their life-history has been obtained during the last half-century. Thus in the case of ferns the male organs, or antheridia, were first discovered by Nägeli in 1844, and the archegonia, or female organs, by Suminski in 1848. The early stages in the development of mosses were worked out by Valentine in 1833. Lastly, the principle of Alternation of Generations in plants was discovered by Hofmeister. This eminent naturalist also, in 1851–4, pointed out the homologies of the reproductive processes in mosses, vascular cryptogams, gymnosperms, and angiosperms.

Nothing could have appeared less likely than that researches into the theory of spontaneous generation should have led to practical improvements in medical science. Yet such has been the case. Only a few years ago Bacteria seemed mere scientific curiosities. It had long been known that an infusion—say, of hay—would, if exposed to the atmosphere, be found, after a certain time, to teem with living forms. Even those few who still believe that life would be spotaneously generated in such an infusion, will admit that these minute organisms are, if not entirely, yet mainly, derived from germs floating in our atmosphere; and if precautions are taken to exclude such germs, as in the careful experiments especially of Pasteur, Tyndall, and Roberts, every one will grant that in ninety-nine cases out of a hundred no such development of life will take place.

These facts have led to most important results in Surgery. One reason why compound fractures are so dangerous, is because, the skin being broken, the air obtains access to the wound, bringing with it innumerable germs, which too often set up putrefying action. Lister first made a practical application of these observations. He set himself to find some substance capable of killing the germs, without being itself too potent a caustic, and he found that dilute carbolic acid fulfilled these conditions. This discovery has enabled many operations to be performed which would previously have been almost hopeless.

The same idea seems destined to prove as useful in Medicine as in Surgery. There is great reason to suppose that many diseases, especially those of a zymotic character, have their origin in the germs of special organisms. We know that fevers run a certain definite course. The parasitic organisms are at first few, but gradually multiply at the expense of the patient, and then die out again. Indeed, it seems to be thoroughly established that many diseases are due to the excessive multiplication of microscopic organisms, and we are not without hope that means will be discovered by which, without injury to the patient, these terrible, though minute, enemies may be destroyed, and the disease thus stayed. The interesting researches of Burdon Sanderson, Greenfield, Koch, Pasteur, Toussaint, and others, seem to justify the hope that we may be able to modify these and other germs, and then by appropriate inoculation to protect ourselves against fever and other acute diseases.

The history of Anæsthetics is a most remarkable illustration of how long we may be on the very verge of a most important discovery. Ether, which, as we all know, produces perfect insensibility to pain, was discovered as long ago as 1540. The anæsthetic property of nitrous oxide, now so extensively used, was observed in 1800 by Sir H. Davy, who actually experimented on himself, and had one of his teeth painlessly extracted when under its influence. He even suggests that "as nitrous oxide gas seems capable of destroying pain, it could probably be used with advantage in surgical operations." Nay, this property of nitrous oxide was habitually explained and illustrated in the chemical lectures given in hospitals, and yet for fifty years the gas was never used in actual operations.

Few branches of science have made more rapid progress in the last half-century than that which deals with the ancient condition of man. When our Association was founded it was generally considered that the human race suddenly appeared on the scene, about 6000 years ago, after the disappearance of the extinct mammalia, and when Europe, both as regards physical conditions and the other animals by which it was inhabited, was pretty much in the same condition as in the period covered by Greek and Roman history. Since then the persevering researches of Layard, Rawlinson, Botta and others have made known to us, not only the statues and palaces of the ancient Assyrian monarchs, but even their libraries; the cuneiform characters have been deciphered, and we can not only see, but read in the British Museum, the actual contemporary records, on burnt clay cylinders, of the events recorded in the historical books of the Old Testament and in the pages of Herodotus. The researches in Egypt also seem to have satisfactorily established the fact that the pyramids themselves are at least 6000 years old, while it is obvious that the Assyrian and Egyptian monarchies cannot suddenly have attained to the wealth and power, the state of social organisation, and progress in the arts, of which we have before us, preserved by the sand of the desert from the ravages of man, such wonderful proofs.

In Europe, the writings of the earliest historians and poets indicated that, before iron came into general use, there was a time when bronze was the ordinary material of weapons, axes, and other cutting implements, and though it seemed *à priori* improbable that a compound of copper and tin should have preceded the simple metal iron, nevertheless the researches of archæologists have shown that there really was in Europe a "Bronze Age," which at the dawn of history was just giving way to that of "Iron."

The contents of ancient graves, buried in many cases so that their owner might carry some at least of his wealth with him to the world of spirits, left no room for doubt as to the existence of a Bronze Age; but we get a completer idea of the condition of Man at this period from the Swiss lake-villages, first made known to us by Keller. Along the shallow edges of the Swiss lakes there flourished, once upon a time, many populous villages or towns, built on platforms supported by piles, exactly as many Malayan villages are now. Under these circumstances innumerable objects were one by one dropped into the water; sometimes whole villages were burnt, and their contents submerged; and thus we have been able to recover, from the waters of oblivion in which they had rested for more than 2000 years, not only the arms and tools of this ancient people, the bones of their animals, their pottery and ornaments, but the stuffs they wore, the grain they had stored up for future use, even fruits and cakes of bread.

But this bronze-using people were not the earliest occupants of Europe. The contents of ancient tombs give evidence of a time when metal was unknown. This also was confirmed by the evidence then unexpectedly received from the Swiss lakes. By the side of the bronze-age villages were others, not less extensive, in which, while implements of stone and bone were discovered literally by thousands, not a trace of metal was met with. The shell-mounds or refuse-heaps accumulated by the ancient fishermen along the shores of Denmark, fully confirmed the existence of a "Stone Age."

No bones of the reindeer, no fragment of any of the extinct mammalia, have been found in any of the Swiss lake-villages or in any of the thousands of tumuli which have been opened in our own country or in Central and Southern Europe. Yet the contents of caves and of river-gravels afford abundant evidence that there was a time when the mammoth and rhinoceros, the musk-ox and reindeer, the cave lion and hyena, the great bear and the gigantic Irish elk wandered in our woods and valleys, and the hippopotamus floated in our rivers; when England and France were united, and the Thames and the Rhine had a common estuary. This was long supposed to be before the advent of Man. At length, however, the discoveries of Boucher de Perthes in the

valley of the Somme, supported as they are by the researches of many Continental naturalists, and in our own country of MacEnery and Godwin-Austen, Prestwich and Lyell, Vivian and Pengelly, Christy, Evans, and many more, have proved that Man formed a humble part of this strange assembly.

Nay, even at this early period there were at least two distinct races of men in Europe; one of them—as Boyd Dawkins has pointed out—closely resembling the modern Esquimaux in form, in his weapons and implements, probably in his clothing, as well as in so many of the animals with which he was associated.

At this stage Man appears to have been ignorant of pottery, to have had no knowledge of agriculture, no domestic animals, except perhaps the dog. His weapons were the axe, the spear, and the javelin; I do not believe he knew the use of the bow, though he was probably acquainted with the lance. He was, of course, ignorant of metal, and his stone implements, though skilfully formed, were of quite different shapes from those of the second Stone age, and were never ground. This earlier Stone period, when man co-existed with these extinct mammalia, is known as the Palæolithic, or Early Stone Age, in opposition to the Neolithic, or Newer Stone Age.

The remains of the mammalia which co-existed with Man in pre-historic times have been most carefully studied by Owen, Lartet, Rütimeyer, Falconer, Busk, Boyd Dawkins, and others. The presence of the mammoth, the reindeer, and especially of the musk-ox, indicates a severe, not to say an arctic, climate, the existence of which, moreover, was proved by other considerations; while, on the contrary, the hippopotamus requires considerable warmth. How then is this association to be explained?

While the climate of the globe is, no doubt, much affected by geographical conditions, the cold of the glacial period was, I believe, mainly due to the excentricity of the earth's orbit, combined with the obliquity of the ecliptic. The result of the latter condition is a period of 21,000 years, during one half of which the northern hemisphere is warmer than the southern, while during the other 10,500 years the reverse is the case. At present we are in the former phase, and there is, we know, a vast accumulation of ice at the south pole. But when the earth's orbit is nearly circular, as it is at present, the difference between the two hemispheres is not very great; on the contrary, as the excentricity of the orbit increases the contrast between them increases also. This excentricity is continually oscillating within certain limits, which Croll and subsequently Stone have calculated out for the last million years. At present the excentricity is ·016 and the mean temperature of the coldest month in London is about 40°. Such has been the state of things for nearly 100,000 years; but before that there was a period, beginning 300,000 years ago, when the excentricity of the orbit varied from ·26 to ·57. The result of this would be greatly to increase the effect due to the obliquity of the orbit; at certain periods the climate would be much warmer than at present, while at others the number of days in winter would be twenty more, and of summer twenty less than now, while the mean temperature of the coldest month would be lowered 20°. We thus get something like a date for the last glacial epoch, and we see that it was not simply a period of cold, but rather one of extremes, each beat of the pendulum of temperature lasting for no less than 21,000 years. This explains the fact that, as Morlot showed in 1854, the glacial deposits of Switzerland, and, as we now know, those of Scotland, are not a single uniform layer, but a succession of strata indicating very different conditions. I agree also with Croll and Geikie in thinking that these considerations explain the apparent anomaly of the co existence in the same gravels of arctic and tropical animals; the former having lived in the cold, while the latter flourished in the hot, periods.

It is, I think, now well established that man inhabited Europe during the milder periods of the glacial epoch. Some high authorities indeed consider that we have evidence of his presence in pre-glacial and even in Miocene times, but I confess that I am not satisfied on this point. Even the more recent period carries back the record of man's existence to a distance so great as altogether to change our views of ancient history.

Nor is it only as regards the antiquity and material condition of man in prehistoric times that great progress has been made. If time permitted I should have been glad to have dwelt on the origin and development of language, of custom, and of law. On all of these the comparison of the various lower races still inhabiting so large a portion of the earth's surface, has thrown much light; while even in the most cultivated nations we find survivals, curious fancies, and lingering ideas; the fossil remains as it were of former customs and religions embedded in our modern civilisation, like the relics of extinct animals in the crust of the earth.

In Geology the formation of our Association coincided with the appearance of Lyell's "Principles of Geology," the first volume of which was published in 1830, and the second in 1832. At that time the received opinion was that the phenomena of Geology could only be explained by violent periodical convulsions, and a high intensity of terrestrial energy culminating in repeated catastrophes. Hutton and Playfair had indeed maintained that such causes as those now in operation would, if only time enough were allowed, account for the geological structure of the earth; nevertheless the opposite view generally prevailed, until Lyell, with rare sagacity and great eloquence, with a wealth of illustration and most powerful reasoning, convinced geologists that the forces now in action are powerful enough, if only time be given, to produce results quite as stupendous as those which science records.

As regards Stratigraphical Geology, at the time of the first meeting of the British Association at York, the strata between the Carboniferous Limestone and the Chalk had been mainly reduced to order and classified, chiefly through the labours of William Smith. But the classification of all the strata lying above the Chalk and below the Carboniferous Limestone respectively, remained in a state of the greatest confusion. The year 1831 marks the period of the commencement of the joint labours of Sedgwick and Murchison, which resulted in the establishment of the Cambrian, Silurian, and Devonian systems. Our pre-Cambrian strata have recently been divided by Hicks into four great groups of immense thickness, and implying, therefore, a great lapse of time; but no fossils have yet been discovered in them. Lyell's classification of the Tertiary deposits, the result of the studies which he carried on with the assistance of Deshayes and others, was published in the third volume of the "Principles of Geology" in 1833. The establishment of Lyell's divisions of Eocene, Miocene, and Pliocene, was the starting-point of a most important series of investigations by Prestwich and others of these younger deposits; as well as of the post-Tertiary, Quaternary, or drift beds, which are of special interest from the light they have thrown on the early history of Man.

As regards the physical character of the earth, two theories have been held: one, that of a fluid interior covered by a thin crust; the other, of a practically solid sphere. The former is now very generally admitted, both by astronomers and geologists, to be untenable. The prevailing feeling of geologists on this subject has been well expressed by Prof. Le Conte, who says, "the whole theory of igneous agencies—which is little less than the whole foundation of theoretic geology—must be reconstructed on the basis of a solid earth."

In 1837 Agassiz startled the scientific world by his "Discours sur l'ancienne extension des Glaciers," in which, developing the observation already made by Charpentier and Venetz, that boulders had been transported to great distances, and that rocks far away from, or high above, existing glaciers, are polished and scratched by the action of ice, he boldly asserted the existence of a "glacial period," during which Switzerland and the North of Europe were subjected to great cold and buried under a vast sheet of ice.

The ancient poets described certain gifted mortals as privileged to descend into the interior of the earth, and have exercised their imagination in recounting the wonders there revealed. As in other cases, however, the realities of science have proved more varied and surprising than the dreams of fiction. Of the gigantic and extraordinary animals thus revealed to us by far the greatest number have been described during the period now under review. For instance, the gigantic Cetiosaurus was described by Owen in 1838, the Dinornis of New Zealand by the same distinguished naturalist in 1839, the Mylodon in the same year, and the Archæopteryx in 1862.

In America, a large number of remarkable forms have been described, mainly by Marsh, Leidy, and Cope. Marsh has made known to us the Titanosaurus, of the American (Colorado) Jurassic beds, which is, perhaps, the largest land animal yet known, being a hundred feet in length, and at least thirty in height, though it seems possible that even these vast dimensions were exceeded by those of the Atlantosaurus. Nor must I omit the Hesperornis, described by Marsh in 1872, as a carnivorous, swimming ostrich, provided with teeth, which he regards as a character inherited from reptilian ancestors; the Ichthyornis,

tranger still, with biconcave vertebræ, like those of fishes, and teeth set in sockets.

As giving, in a few words, an idea of the rapid progress in this department, I may mention that Morris's "Catalogue of British Fossils," published in 1843, contained 5300 species; while that now in preparation by Mr. Etheridge enumerates 15,000.

But if these figures show how rapid our recent progress has been, they also very forcibly illustrate the imperfection of the geological record, and give us, I will not say a measure, but an idea, of the imperfection of the geological record. The number of all the described recent species is over 300,000, but certainly not half are yet on our lists, and we may safely take the total number of recent species as being not less than 700,000. But in former times there have been at the very least twelve periods, in each of which by far the greater number of species were distinct. True, the number of species was probably not so large in the earlier periods as at present; but if we make a liberal allowance for this, we shall have a total of more than 2,000,000 species, of which about 25,000 only are as yet upon record; and many of these are only represented by a few, some only by a single specimen, or even only by a fragment.

The progress of palæontology may also be marked by the extent to which the existence of groups has been, if I may so say, carried back in time. Thus I believe that in 1830 the earliest known quadrupeds were small marsupials belonging to the Stonesfield slates; the most ancient mammal now known is *Microlestes antiquus* from the Keuper of Würtemberg: the oldest bird known in 1831 belonged to the period of the London Clay, the oldest now known is the Archæopteryx of the Solenhofen slates, though it is probable that some at any rate of the foot-steps on the Triassic rocks are those of birds. So again the Amphibia have been carried back from the Trias to the Coal-measures; Fish from the Old Red Sandstone to the Upper Silurian; Reptiles to the Trias; Insects from the Cretaceous to the Devonian; Mollusca and Crustacea from the Silurian to the Lower Cambrian. The rocks below the Cambrian, though of immense thickness, have afforded no relics of animal life, if we except the problematical *Eozoon Canadense*, so ably studied by Dawson and Carpenter. But if palæontology as yet throws no light on the original forms of life, we must remember that the simplest and the lowest organisms are so soft and perishable that they would leave "not a wrack behind."

Passing to the science of Geography, Mr. Clements Markham has recently published an excellent summary of what has been accomplished during the half-century.

But the progress in our knowledge of geography is, and has been, by no means confined to the improvement of our maps, or to the discovery and description of new regions of the earth, but has extended to the causes which have led to the present configuration of the surface. To a great extent indeed this part of the subject falls rather within the scope of geology, but I may here refer, in illustration, to the distribution of lakes, the phenomena of glaciers, the formation of volcanic mountains, and the structure and distribution of coral islands.

The origin and distribution of lakes is one of the most interesting problems in physical geography. That they are not scattered at random, a glance at the map is sufficient to show. They abound in mountain districts, are comparatively rare in equatorial regions, increasing in number as we go north, so that in Scotland and the northern parts of America they are sown broadcast.

Perhaps *à priori* the first explanation of the origin of lakes which would suggest itself, would be that they were formed in hollows resulting from a disturbance of the strata, which had thrown them into a basin-shaped form. Lake-basins, however, of this character are, as a matter of fact, very rare; as a general rule lakes have not the form of basin-shaped synclinal hollows, but, on the contrary, the strike of the strata often runs right across them. My eminent predecessor, Prof. Ramsay, divides lakes into three classes:—(1) Those which are due to irregular accumulations of drift, and which are generally quite shallow. (2) Those which are formed by moraines, and (3) those which occupy true basins scooped by glacier-ice out of the solid rock. To the latter class belong most of the great Swiss and Italian lakes. Prof. Ramsay attributes their excavation to glaciers, because it is of course obvious that rivers cannot make basin-shaped hollows surrounded by rock on all sides. Now the Lake of Geneva, 1230 feet above the sea, is 984 feet deep, the Lake of Brienz is 1850 feet above the sea, and 2000 feet deep, so that its bottom is really below the sea-level. The Italian lakes are even more remarkable. The Lake of Como, 700 feet above the sea, is 1929 feet deep. Lago Maggiore, 685 feet above the sea, is no less than 2625 feet deep. It will be observed that these lakes, like many others in mountain regions, those of Scandinavia, for instance, lie in the direct channels of the great old glaciers. If the mind is at first staggered at the magnitude of the scale, we must remember that the ice which scooped out the valley in which the Lake of Geneva now reposes, was once at least 2700 feet thick; while the moraines were also of gigantic magnitude, that of Ivrea, for instance, being no less than 1500 feet in height. Prof. Ramsay's theory seems, therefore, to account beautifully for a large number of interesting facts.

Passing from lakes to mountains, two rival theories with reference to the structure and origin of volcanoes long struggled for supremacy.

The more general view was that the sheets of lava and scoriæ which form volcanic cones—such, for instance, as Ætna or Vesuvius—were originally nearly horizontal, and that subsequently a force operating from below, and exerting a pressure both upwards and outwards from a central axis towards all points of the compass, uplifted the whole stratified mass and made it assume a conical form, giving rise at the same time, in many cases, to a wide and deep circular opening at the top of the cone, called by the advocates of this hypothesis a "crater of elevation."

This theory, though, as it seems to us now, it had already received its death-blow from the admirable memoirs of Scrope, was yet that most generally adopted fifty years ago, because it was considered that compact and crystalline lavas could not have consolidated on a slope exceeding 1° or 2°. In 1858, however, Sir C. Lyell conclusively showed that in fact such lavas could consolidate at a considerable angle, even in some cases at more than 30°, and it is now generally admitted that though the beds of lava, &c, may have sustained a slight angular elevation since their deposition, still in the main, volcanic cones have acquired their form by the accumulation of lava and ashes ejected from one or more craters.

The problems presented by glaciers are of very great interest. In 1843 Agassiz and Forbes proved that the centre of a glacier, like that of a river, moves more rapidly than its sides. But how and why do glaciers move at all? Rendu, afterwards Bishop of Annecy, in 1841 endeavoured to explain the facts by supposing that glacier ice enjoys a kind of ductility. The "viscous theory" of glaciers was also adopted, and most ably advocated, by Forbes, who compared the condition of a glacier to that of the contents of a tar-barrel poured into a sloping channel. We have all, however, seen long narrow fissures, a mere fraction of an inch in width, stretching far across glaciers—a condition incompatible with the ordinary idea of viscosity. The phenomenon of regelation was afterwards applied to the explanation of glacier motion. An observation of Faraday's supplied the clue. He noticed in 1850 that when two pieces of thawing ice are placed together they unite by freezing at the place of contact. Following up this suggestion, Tyndall found that if he compressed a block of ice in a mould it could be made to assume any shape he pleased. A straight prism, for instance, placed in a groove and submitted to hydraulic pressure, was bent into a transparent semicircle of ice. These experiments seem to have proved that a glacial valley is a mould through which the ice is forced, and to which it will accommodate itself, while as Tyndall and Huxley also pointed out, the "veined structure of ice" is produced by pressure, in the same manner as the cleavage of slate rocks.

It was in the year 1842 that Darwin published his great work on "Coral Islands." The fringing reefs of coral presented no special difficulty. They could be obviously accounted for by an elevation of the land, so that the coral which had originally grown under water, had been raised above the sea-level. The circular or oval shape of so many reefs, however, each having a lagoon in the centre, closely surrounded by a deep ocean, and rising but a few feet above the sea-level, had long been a puzzle to the physical geographer. The favourite theory was that these were the summits of submarine volcanoes on which the coral had grown. But as the reef-making coral does not live at greater depths than about twenty-five fathoms, the immense number of these reefs formed an almost insuperable objection to this theory. The Laccadives and Maldives, for instance—meaning literally the "lac of islands" and the "thousand islands"—are a series of such

atolls, and it was impossible to imagine so great a number of craters, all so nearly of the same altitude. Darwin showed, moreover, that so far from the ring of corals resting on a corresponding ridge of rock, the lagoons, on the contrary, now occupy the place which was once the highest land. He pointed out that some lagoons, as, for instance, that of Vanikoro, contain an island in the middle; while other islands, such as Tahiti, are surrounded by a margin of smooth water, separated from the ocean by a coral reef. Now, if we suppose that Tahiti were to sink slowly, it would gradually approximate to the condition of Vanikoro; and if Vanikoro gradually sank, the central island would disappear, while on the contrary the growth of the coral might neutralise the subsidence of the reef, so that we should have simply an atoll, with its lagoon. The same considerations explain the origin of the "barrier reefs," such as that which runs, for nearly one thousand miles, along the north-east coast of Australia. Thus Darwin's theory explained the form and the approximate identity of altitude of these coral islands. But it did more than this, because it showed us that there were great areas in process of subsidence, which though slow, was of great importance in physical geography.[1]

Much information has also been acquired with reference to the abysses of the ocean, especially from the voyages of the *Porcupine* and the *Challenger*. The greatest depth yet recorded is near the Ladrone Islands, where a sounding of 4575 fathoms was obtained.

Ehrenberg long ago pointed out the similarity of the calcareous mud now accumulating in our recent seas to the Chalk, and showed that the green sands of the geologist are largely made up of casts of foraminifera. Clay, however, had been looked on, until the recent expeditions, as essentially a product of the disintegration of older rocks. Not only, however, are a large proportion of siliceous and calcareous rocks either directly or indirectly derived from material which has once formed a portion of living organisms, but Sir Wyville Thomson maintains that this is the case with some clays also. In that case the striking remark of Linnæus, that "fossils are not the children but the parents of rocks," will have received remarkable confirmation. I should have thought it, I confess, probable that these clays are, to a considerable extent, composed of volcanic dust.

It would appear that calcareous deposits resembling our chalk do not occur at a greater depth than 3000 fathoms; they have not been met with in the abysses of the ocean. Here the bottom consists of exceedingly fine clay, sometimes coloured red by oxide of iron, sometimes chocolate by manganese oxide, and containing with Foraminifera occasionally large numbers of siliceous Radiolaria. These strata seem to accumulate with extreme slowness: this is inferred from the comparative abundance of whales' bones and fishes' teeth; and from the presence of minute spherical particles, supposed by Mr. Murray to be of cosmic origin—in fact, to be the dust of meteorites, which in the course of ages have fallen on the ocean. Such particles no doubt occur over the whole surface of the earth, but on land they soon oxidise, and in shallow water they are covered up by other deposits. Another interesting result of recent deep-sea explorations has been to show that the depths of the ocean are no mere barren solitudes, as was until recent years confidently believed, but, on the contrary, present us many remarkable forms of life. We have, however, as yet but thrown here and there a ray of light down into the ocean abysses:—

> "Nor can so short a time sufficient be,
> To fathom the vast depths of Nature's sea."

In Astronomy, the discovery in 1845 of the planet Neptune, made independently and almost simultaneously by Adams and by Le Verrier, was certainly one of the very greatest triumphs of mathematical genius. Of the minor planets four only were known in 1831, whilst the number now on the roll amounts to 220. Many astronomers believe in the existence of an intramercurial planet or planets, but this is still an open question. The Solar System has also been enriched by the discovery of an inner ring to Saturn, of satellites to Mars, and of additional satellites to Saturn, Uranus and Neptune.

The most unexpected progress, however, in our astronomical knowledge during the past half-century has been due to Spectrum Analysis.

The dark lines in the spectrum were first seen by Wollaston, who noticed a few of them; but they were independently discovered by Fraunhofer, after whom they are justly named, and who, in 1814, mapped no fewer than 576. The first steps in "spectrum analysis," properly so called, were made by Sir J. Herschel, Fox Talbot, and by Wheatstone, in a paper read before this Association in 1835. The latter showed that the spectrum emitted by the incandescent vapour of metals was formed of bright lines, and that these lines, while, as he then supposed, constant for each metal, differed for different metals. "We have here," he said, "a mode of discriminating metallic bodies more readily than that of chemical examination, and which may hereafter be employed for useful purposes." Nay, not only can bodies thus be more readily discriminated, but, as we now know, the presence of extremely minute portions can be detected, the $\frac{1}{5000000}$th of a grain being in some cases easily perceptible.

It is also easy to see that the presence of any new simple substance might be detected, and in this manner already several new elements have been discovered, as I shall mention when we come to Chemistry.

But spectrum analysis has led to even grander and more unexpected triumphs. Fraunhofer himself noticed the coincidence between the double dark line D of the solar spectrum and a double line which he observed in the spectra of ordinary flames, while Stokes pointed out to Sir W. Thomson, who taught it in his lectures, that in both cases these lines were due to the presence of sodium. To Kirchhoff and Bunsen, however, is due the independent conception and the credit of having first systematically investigated the relation which exists between Fraunhofer's lines and the bright lines in the spectra of incandescent metals. In order to get some fixed measure by which they might determine and record the lines characterising any given substance, it occurred to them that they might use for comparison the spectrum of the sun. They accordingly arranged their spectroscope so that one-half of the slit was lighted by the sun, and the other by the luminous gases they proposed to examine. It immediately struck them that the bright lines in the one corresponded with the dark lines in the other—the bright line of sodium, for instance, with the line or rather lines D in the sun's spectrum. The conclusion was obvious. There was sodium in the sun! It must indeed have been a glorious moment when that thought flashed across them, and even by itself well worth all their labour.

Kirchhoff and Bunsen thus proved the existence in the sun of hydrogen, sodium, magnesium, calcium, iron, nickel, chromium, manganese, titanium, and cobalt; since which Ångström, Thalèn, and Lockyer have considerably increased the list.

But it is not merely the chemistry of the heavenly bodies on which light is thrown by the spectroscope; their physical structure and evolutional history are also illuminated by this wonderful instrument of research.

It used to be supposed that the sun was a dark body enveloped in a luminous atmosphere. The reverse now appears to be the truth. The body of the sun, or photosphere, is intensely brilliant; round it lies the solar atmosphere of comparatively cool gases, which cause the dark lines in the spectrum; thirdly, a chromosphere,—a sphere principally of hydrogen, jets of which are said sometimes to reach to a height of 100,000 miles or more, into the outer coating or corona, the nature of which is still very doubtful.

Formerly the red flames which represent the higher regions of the chromosphere could be seen only on the rare occasions of a total solar eclipse. Janssen and Lockyer, by the application of the spectroscope, have enabled us to study this region of the sun at all times.

It is, moreover, obvious that the powerful engine of investigation afforded us by the spectroscope is by no means confined to the substances which form part of our system. The incandescent body can thus be examined, no matter how great its distance, so long only as the light is strong enough. That this method was theoretically applicable to the light of the stars was indeed obvious, but the practical difficulties were very great. Sirius, the brightest of all, is, in round numbers, a hundred millions of millions of miles from us; and, though as big as sixty of our suns, his light when it reaches us, after a journey of sixteen years, is at most one two-thousand-millionth part as bright. Nevertheless as long ago as 1815 Fraunhofer recognised the fixed lines in the light of four of the stars, and in 1863 Miller and Huggins in our own country, and Rutherford in America, succeeded in determining the dark lines in the spectrum of some of the brighter stars, thus showing that these beautiful and mysterious lights contain many of the material substances with

[1] I ought to mention that Darwin's views have recently been questioned by Semper and Murray.

which we are familiar. In Aldebaran, for instance, we may infer the presence of hydrogen, sodium, magnesium, iron, calcium, tellurium, antimony, bismuth, and mercury; some of which are not yet known to occur in the sun. As might have been expected, the composition of the stars is not uniform, and it would appear that they may be arranged in a few well-marked classes, indicating differences of temperature, or in other words, of age. Some recent photographic spectra of stars obtained by Huggins go very far to justify this view.

Thus we can make the stars teach us their own composition with light which started from its source before we were born—light older than our Association itself.

But spectrum analysis has even more than this to tell us. The old methods of observation could determine the movements of the stars so far only as they were transverse to us; they afforded no means of measuring motion either directly towards or away from us. Now Döppler suggested in 1841 that the colours of the stars would assist us in this respect, because they would be affected by their motion to and from the earth, just as a steam-whistle is raised or lowered as it approaches or recedes from us. Every one has observed that if a train whistles as it passes us, the sound appears to alter at the moment the engine goes by. This arises, of course, not from any change in the whistle itself, but because the number of vibrations which reach the ear in a given time are increased by the speed of the train as it approaches, and diminished as it recedes. So like the sound, the colour would be affected by such a movement; but Döppler's method was practically inapplicable, because the amount of effect on the colour would be utterly insensible; and even if it were otherwise the method could not be applied, because, as we did not know the true colour of the stars, we have no datum line by which to measure.

A change of refrangibility of light, however, does occur in consequence of relative motion, and Huggins successfully applied the spectroscope to solve the problem. He took in the first place the spectroscope of Sirius, and chose a line known as F, which is due to hydrogen. Now, if Sirius was motionless, or rather if it retained a constant distance from the earth, the line F would occupy exactly the same position in the spectrum of Sirius, as in that of the sun. On the contrary, if Sirius were approaching or receding from us, this line would be slightly shifted either towards the blue or red end of the spectrum. He found that the line had moved very slightly towards the red, indicating that the distance between us and Sirius is increasing at the rate of about twenty miles a second. So also Betelgeux, Rigel, Castor, and Regulus are increasing their distance; while, on the contrary, that of others, as for instance of Vega, Arcturus, and Pollux, is diminishing. The results obtained by Huggins on about twenty stars have since been confirmed and extended by Mr. Christie, now Astronomer-Royal in succession to Sir G. Airy, who has long occupied the post with so much honour to himself and advantage to science.

To examine the spectrum of a shooting star would seem even more difficult; yet Alexander Herschel has succeeded in doing so, and finds that their nuclei are incandescent solid bodies; he has recognised the lines of potassium, sodium, lithium, and other substances, and considers that the shooting stars are bodies similar in character and composition to the stony masses which sometimes reach the earth as aërolites.

No element has yet been found in any meteorite, which was not previously known as existing in the earth, but the phenomena which they exhibit indicate that they must have been formed under conditions very different from those which prevail on the earth's surface. I may mention, for instance, the peculiar form of crystallised silica, called by Maskelyne, Asmanite; and the whole class of meteorites, consisting of iron generally alloyed with nickel, which Daubrée terms Holosiderites. The interesting discovery, however, by Nordenskjöld, in 1870, at Ovifak, of a number of blocks of iron alloyed with nickel and cobalt, in connection with basalts containing disseminated iron, has, in the words of Judd, "afforded a very important link, placing the terrestrial and extra-terrestrial rocks in closer relations with one another."

We have as yet no sufficient evidence to justify a conclusion as to whether any substances exist in the heavenly bodies which do not occur in our earth, though there are many lines which cannot yet be satisfactorily referred to any terrestrial element. On the other hand, some substances which occur on our earth have not yet been detected in the sun's atmosphere.

Such discoveries as these seemed, not long ago, entirely beyond our hopes. M. Comte, indeed, in his "Cours de Philosophie Positive," as recently as 1842, laid it down as an axiom regarding the heavenly bodies, that "Nous concevons la possibilité de déterminer leurs formes, leurs distances, leurs grandeurs et leurs mouvements, tandis que nous ne saurions jamais étudier par aucun moyen leur composition chimique ou leur structure minéralogique." Yet within a few years this supposed impossibility has been actually accomplished, showing how unsafe it is to limit the possibilities of science.

It is hardly necessary to point out that, while the spectrum has taught us so much, we have still even more to learn. Why should some substances give few, and others many, lines? Why should the same substance give different lines at different temperatures? What are the relations between the lines and the physical or chemical properties?

We may certainly look for much new knowledge of the hidden actions of atoms and molecules from future researches with the spectroscope. It may even, perhaps, teach us to modify our views of the so-called simple substances. Prout long ago, struck by the remarkable fact that nearly all atomic weights are simple multiples of the atomic weight of hydrogen, suggested that hydrogen must be the primordial substance. Brodie's researches also naturally fell in with the supposition that the so-called simple substances are in reality complex, and that their constituents occur separately in the hottest regions of the solar atmosphere. Lockyer considers that his researches lend great probability to this view. The whole subject is one of intense interest, and we may rejoice that it is occupying the attention, not only of such men as Abney, Dewar, Hartley, Liveing, Roscoe and Schuster in our own country, but also of many foreign observers.

When geology so greatly extended our ideas of past time, the continued heat of the sun became a question of greater interest than ever. Helmholtz has shown that, while adopting the nebular hypothesis, we need not assume that the nebulous matter was originally incandescent; but that its present high temperature may be, and probably is, mainly due to gravitation between its parts. It follows that the potential energy of the sun is far from exhausted, and that with continued shrinking it will continue to give out light and heat, with little, if any, diminution for several millions of years.

Like the sand of the sea, the stars of heaven have ever been used as effective symbols of number, and the improvements in our methods of observation have added fresh force to our original impressions. We now know that our earth is but a fraction of one out of at least 75,000,000 worlds.

But this is not all. In addition to the luminous heavenly bodies, we cannot doubt that there are countless others, invisible to us from their greater distance, smaller size, or feebler light; indeed we know that there are many dark bodies which now emit no light or comparatively little. Thus in the case of Procyon, the existence of an invisible body is proved by the movement of the visible star. Again I may refer to the curious phenomena presented by Algol, a bright star in the head of Medusa. This star shines without change for two days and thirteen hours; then, in three hours and a half, dwindles from a star of the second to one of the fourth magnitude; and then, in another three and a half hours, reassumes its original brilliancy. These changes seem certainly to indicate the presence of an opaque body, which intercepts at regular intervals a part of the light emitted by Algol.

Thus the floor of heaven is not only "thick inlaid with patines of bright gold," but studded also with extinct stars; once probably as brilliant as our own sun, but now dead and cold, as Helmholtz tells us that our sun itself will be, some seventeen millions of years hence.

The general result of astronomical researches has been thus eloquently summed up by Proctor:—"The sidereal system is altogether more complicated and more varied in structure than has hitherto been supposed; in the same region of the stellar depths co-exist stars of many orders of real magnitude; all orders of nebulæ, gaseous or stellar, planetary, ring-formed, elliptical, and spiral, exist within the limits of the galaxy; and lastly, the whole system is alive with movements, the laws of which may one day be recognised, though at present they appear too complex to be understood."

We can, I think, scarcely claim the establishment of the undulatory theory of light as falling within the last fifty years; for though Brewster, in his "Report on Optics," published in our first volume, treats the question as open, and expresses himself

still unconvinced, he was, I believe, almost alone in his preference for the emission theory. The phenomena of interference, in fact, left hardly any—if any—room for doubt, and the subject was finally set at rest by Foucault's celebrated experiments in 1850. According to the undulatory theory the velocity of light ought to be greater in air than in water, while if the emission theory were correct the reverse would be the case. The velocity of light—186,000 miles in a second—is, however, so great that, to determine its rate in air, as compared with that in water, might seem almost hopeless. The velocity in air was, nevertheless, determined by Fizeau in 1849, by means of a rapidly revolving wheel. In the following year Foucault, by means of a revolving mirror, demonstrated that the velocity of light is greater in air than in water—thus completing the evidence in favour of the undulatory theory of light.

The idea is now gaining ground, that, as maintained by Clerk-Maxwell, light itself is an electro-magnetic disturbance, the luminiferous ether being the vehicle of both light and electricity.

Wünsch, as long ago as 1792, had clearly shown that the three primary colours were red, green, and violet; but his results attracted little notice, and the general view used to be that there were seven principal colours—red, orange, yellow, green, blue, indigo, and violet; four of which—namely orange, green, indigo, and violet—were considered to arise from mixtures of the other three. Red, yellow, and blue were therefore called the primary colours, and it was supposed that in order to produce white light these three colours must always be present.

Helmholtz, however, again showed, in 1852, that a colour to our unaided eyes identical with white, was produced by combining yellow with indigo. At that time yellow was considered to be a simple colour, and this, therefore, was regarded as an exception to the general rule, that a combination of three simple colours is required to produce white. Again, it was, and indeed still is, the general impression that a combination of blue and yellow makes green. This, however, is entirely a mistake. Of course we all know that yellow paint and blue paint make green paint; but this results from absorption of light by the semi-transparent solid particles of the pigments, and is not a mere mixture of the colours proceeding unaltered from the yellow and the blue particles: moreover, as can easily be shown by two sheets of coloured paper and a piece of window glass, blue and yellow light, when combined, do not give a trace of green, but if pure would produce the effect of white. Green, therefore, is after all not produced by a mixture of blue and yellow. On the other hand Clerk-Maxwell proved in 1860 that yellow could be produced by a mixture of red and green, which put an end to the pretension of yellow to be considered a primary element of colour. From these and other considerations it would seem, therefore, that the three primary colours—if such an expression be retained—are red, green, and violet.

The existence of rays beyond the violet, though almost invisible to our eyes, had long been demonstrated by their chemical action. Stokes, however, showed in 1852 that their existence might be proved in another manner, for that there are certain substances which, when excited by them, emit light visible to our eyes. To this phenomenon he gave the name of fluorescence. At the other end of the spectrum Abney has recently succeeded in photographing a large number of lines in the infra-red portion, the existence of which was first proved by Sir William Herschel.

From the rarity, and in many cases the entire absence, of reference to blue, in ancient literature, Geiger—adopting and extending a suggestion first thrown out by Mr. Gladstone—has maintained that, even as recently as the time of Homer, our ancestors were blue blind. Though for my part I am unable to adopt this view, it is certainly very remarkable that neither the Rigveda, which consists almost entirely of hymns to heaven, nor the Zendave ta, the Bible of the Parsees or fire-worshippers, nor the Old Testament, nor the Homeric poems, ever allude to the sky as blue.

On the other hand, from the dawn of poetry, the splendours of the morning and evening skies have excited the admiration of mankind. As Ruskin says, in language almost as brilliant as the sky itself, the whole heaven, "from the zenith to the horizon, becomes, one molten, mantling sea of colour and fire; every black bar turns into massy gold, every ripple and wave into unsullied shadowless crimson, and purple, and scarlet, and colours for which there are no words in language, and no ideas in the mind—things which can only be conceived while they are visible; the intense hollow blue of the upper sky melting through it all, showing here deep, and pure, and lightness; there, modulated by the filmy, formless body of the transparent vapour, till it is lost imperceptibly in its crimson and gold."

But what is the explanation of these gorgeous colours? why is the sky blue? and why are the sunrise and sunset crimson and gold? It may be said that the air is blue, but if so how can the clouds assume their varied tints? Brücke showed that very minute particles suspended in water are blue by reflected light. Tyndall has taught us that the blue of the sky is due to the reflection of the blue rays by the minute particles floating in the atmosphere. Now if from the white light of the sun the blue rays are thus selected, those which are transmitted will be yellow, orange, and red. Where the distance is short the transmitted light will appear yellowish. But as the sun sinks towards the horizon the atmospheric distance increases, and consequently the number of the scattering particles. They weaken in succession the violet, the indigo, the blue, and even disturb the proportions of green. The transmitted light under such circumstances must pass from yellow through orange to red, and thus, while we at noon are admiring the deep blue of the sky, the same rays, robbed of their blue, are elsewhere lighting up the evening sky with all the glories of sunset.

Another remarkable triumph of the last half-century has been the discovery of photography. At the commencement of the century Wedgwood and Davy observed the effect produced by throwing the images of objects on paper or leather prepared with nitrate of silver, but no means were known by which such images could be fixed. This was first effected by Niepce, but his processes were open to objections which prevented them from coming into general use, and it was not till 1839 that Daguerre invented the process which was justly named after him. Very soon a further improvement was effected by our countryman Talbot. He not only fixed his "Talbotypes" on paper—in itself a great convenience—but, by obtaining a negative, rendered it possible to take off any number of positive, or natural, copies from one original picture.

We owe to Wheatstone the conception that the idea of solidity is derived from the combination of two pictures of the same object in slightly different perspective. This he proved in 1833 by drawing two outlines of some geometrical figure or other simple object, as they would appear to either eye respectively, and then placing them so that they might be seen, one by each eye. The "stereoscope," thus produced, has been greatly popularised by photography.

For 2000 years the art of lighting had made little if any progress. Until the close of the last century, for instance, our lighthouses contained mere fires of wood or coal, though the construction had vastly improved. The Eddystone lighthouse, for instance, was built by Smeaton in 1759; but for forty years its light consisted in a row of tallow candles stuck in a hoop. The Argand lamp was the first great improvement, followed by gas, and in 1863 by the electric light.

Just as light was long supposed to be due to the emission of material particles, so heat was regarded as a material, though ethereal, substance, which was added to bodies when their temperature was raised.

Davy's celebrated experiment of melting two pieces of ice by rubbing them against one another in the exhausted receiver of an air-pump had convinced him that the cause of heat was the motion of the invisible particles of bodies, as had been long before suggested by Newton, Boyle, and Hooke. Rumford and Young also advocated the same view. Nevertheless, the general opinion, even until the middle of the present century, was that heat was due to the presence of a subtle fluid known as "caloric," a theory which is now entirely abandoned.

The determination of the mechanical equivalent of heat is mainly due to the researches of Mayer and Joule. Mayer, in 1842, pointed out the mechanical equivalent of heat as a fundamental datum to be determined by experiment. Taking the heat produced by the condensation of air as the equivalent of the work done in compressing the air, he obtained a numerical value of the mechanical equivalent of heat. There was, however, in these experiments, one weak point. The matter operated on did not go through a cycle of changes. He assumed that the production of heat was the only effect of the work done in compressing the air. Joule had the merit of being the first to meet this possible source of error. He ascertained that a weight of 1 lb. would have to fall 772 feet in order to raise the temperature of 1 lb. of water by 1° Fahr. Hirn

subsequently attacked the problem from the other side, and showed that if all the heat passing through a steam-engine was turned into work, for every degree Fahr. added to the temperature of a pound of water, enough work could be done to raise a weight of 1 lb. to a height of 772 feet. The general result is that, though we cannot create energy, we may help ourselves to any extent from the great storehouse of nature. Wind and water, the coal-bed and the forest, afford man an inexhaustible supply of available energy.

It used to be considered that there was an absolute break between the different states of matter. The continuity of the gaseous, liquid, and solid conditions was first demonstrated by Andrews in 1862.

Oxygen and nitrogen have been liquefied independently and at the same time by Cailletet and Raoul Pictet. Cailletet also succeeded in liquefying air, and soon afterwards hydrogen was liquefied by Pictet under a pressure of 650 atmospheres, and a cold of 170° Cent. below zero. It even became partly solidified, and he assures us that it fell on the floor with "the shrill noise of metallic hail." Thus then it was shown experimentally that there are no such things as absolutely permanent gases.

The kinetic theory of gases, now generally accepted, refers the elasticity of gases to a motion of translation of their molecules, and we are assured that in the case of hydrogen at a temperature of 60° Fahr. they move at an average rate of 6225 feet in a second; while as regards their size, Loschmidt, who has since been confirmed by Stoney and Sir W. Thomson, calculates that each is at most 1-500000000th of an inch in diameter.

We cannot, it would seem at present, hope for any increase of our knowledge of atoms by any improvement in the microscope. With our present instruments we can perceive lines ruled on glass of 1-90,000th of an inch apart. But, owing to the properties of light itself, the fringes due to interference begin to produce confusion at distances of 1-74,000. It would seem then that, owing to the physical characters of light, we can, as Sorby has pointed out, scarcely hope for any great improvement so far as the mere visibility of structure is concerned, though in other respects no doubt much may be hoped for. At the same time, Dallinger and Royston Pigott have shown that, so far as the mere presence of simple objects is concerned, bodies of even smaller dimensions can be perceived.

Sorby is of opinion that in a length of 1-80,000th of an inch there would probably be from 500 to 2000 molecules—500, for instance, in albumen and 2000 in water. Even, then, if we could construct microscopes far more powerful than any we now possess, they would not enable us to obtain by direct vision any idea of the ultimate molecules of matter. Sorby calculates that the smallest sphere of organic matter which could be clearly defined with our most powerful microscopes would contain many millions of molecules of albumen and water, and it follows that there may be an almost infinite number of structural characters in organic tissues, which we can at present foresee no mode of examining.

Electricity in the year 1831 may be considered to have just been ripe for its adaptation to practical purposes; it was but a few years previously, in 1819, that Oersted had discovered the deflective action of the current on the magnetic needle, that Ampère had laid the foundation of electro-dynamics, that Schweizzer had devised the electric coil or multiplier, and that Sturgeon had constructed the first electro-magnet. It was in 1831 that Faraday, the prince of pure experimentalists, announced his discoveries of voltaic induction and magneto-electricity, which with the other three discoveries constitute the principles of nearly all the telegraph instruments now in use; and in 1834 our knowledge of the nature of the electric current had been much advanced by the interesting experiment of Sir Charles Wheatstone, proving the velocity of the current in a metallic conductor to approach that of the wave of light.

Practical applications of these discoveries were not long in coming to the fore, and the first telegraph line on the Great Western Railway from Paddington to West Drayton was set up in 1838. In America Morse is said to have commenced to develop his recording instrument between the years 1832 and 1837.

In 1851, submarine telegraphy became an accomplished fact through the successful establishment of telegraphic communication between Dover and Calais. Submarine lines followed in rapid succession, crossing the English Channel and the German Ocean, threading their way through the Mediterranean, Black and Red Seas, until in 1866, after two abortive attempts telegraphic communication was successfully established between the Old and New Worlds, beneath the Atlantic Ocean.

Duplex and quadruplex telegraphy, one of the most striking achievements of modern telegraphy, the result of the labours of several inventors, should not be passed over in silence. It not only serves for the simultaneous communication of telegraphic intelligence in both directions, but renders it possible for four instruments to be worked irrespectively of one another, through one and the same wire connecting to distant places.

Another more recent and perhaps still more wonderful achievement in modern telegraphy is the invention of the telephone and microphone, by means of which the human voice is transmitted through the electric conductor, by mechanism that imposes through its extreme simplicity. In this connection the names of Reiss, Graham Bell, Edison, and Hughes are those chiefly deserving to be recorded.

By the electric transmission of power, we may hope some day to utilise at a distance such natural sources of energy as the Falls of Niagara, and to work our cranes, lifts, and machinery of every description by means of sources of power arranged at convenient centres. To these applications the brothers Siemens have more recently added the propulsion of trains by currents passing through the rails, the fusion in considerable quantities of highly refractory substances, and the use of electric centres of light in horticulture as proposed by Werner and William Siemens. By an essential improvement by Faure of the Planté Secondary Battery, the problem of storing electrical energy appears to have received a practical solution, the real importance of which is clearly proved by Sir W. Thomson's recent investigation of the subject

It would be difficult to assign the limits to which this development of electrical energy may not be rendered serviceable for the purposes of man.

As regards Mathematics I have felt that it would be impossible for me, even with the kindest help, to write anything myself. Mr. Spottiswoode, however, has been so good as to supply me with the following memorandum.

In a complete survey of the progress of science during the half-century which has intervened between our first and our present meeting, the part played by mathematics would form no insignificant feature. To those indeed who are outside its enchanted circle it is difficult to realise the intense intellectual energy which actuates its devotees, or the wide expanse over which that energy ranges.

In the extension of mathematics it has happened more than once that laws have been established so simple in form, and so obvious in their necessity, as scarcely to require proof. And yet their application is often of the highest importance in checking conclusions which have been drawn from other considerations, as well as in leading to conclusions which, without their aid, might have been difficult of attainment. The same thing has occurred also in physics; and notably in the recognition of what has been termed the "Law of the Conservation of Energy."

Energy has been defined to be "The capacity, or power, of any body, or system of bodies, when in a given condition, to do a measurable quantity of work." Such work may either change the condition of the bodies in question, or it may affect other bodies; but in either case energy is expended by the agent upon the recipient in performance of the work. The law then states that the total amount of energy in the agents and recipients taken together remains unaltered by the changes in question.

Now the principle on which the law depends is this: "that every kind of change among the bodies may be expressed numerically in one standard unit of change," viz., work done, in such wise that the result of the passage of any system from one condition to another may be calculated by mere additions and subtractions, even when we do not know how the change came about.

The history of a discovery, or invention, so simple at first sight, is often found to be more complicated the more thoroughly it is examined. That which at first seems to have been due to a single mind proves to have been the result of the successive action of many minds. Attempts more or less successful in the same direction are frequently traced out; and even unsuccessful efforts may not have been without influence on minds turned towards the same object. Lastly also, germs of thought, originally not fully understood, sometimes prove in the end to have been the first stages of growth towards ultimate fruit. The history of the law of the conservation of energy forms no

exception to this order of events. There are those who discern even in the writings of Newton expressions which show that he was in possession of some ideas which, if followed out in a direct line of thought, would lead to those now entertained on the subjects of energy and of work. But however this may be, and whosoever might be reckoned among the earlier contributors to the general subject of energy, and to the establishment of its laws, it is certain that within the period of which I am now speaking, the names of Séguin, Clausius, Helmholtz, Mayer, and Colding, on the Continent, and those of Grove, Joule, Rankine, and Thomson, in this country, will always be associated with this great work.

Prof. Frankland has been so good as to draw up for me the following account of the progress of Chemistry during the last half-century.

Most of the elements had been discovered before 1830, the majority of the rarer elements since the beginning of the century. In addition to these the following five have been discovered, three of them by Mosander, viz.:—lanthanum in 1839, didymium in 1842, and erbium in 1843. Ruthenium was discovered by Claus in 1843, and niobium by Rose in 1844. Spectrum analysis has added five to the list, viz.:—Cæsium and rubidium, which were discovered by Bunsen and Kirchhoff in 1860; thallium, by Crookes in 1861; indium, by Reich and Richter in 1863; and gallium, by Lecoq de Boisbaudran in 1875.

In organic chemistry the views most generally held about the year 1830 were expressed in the radical theory of Berzelius. This theory, which was first stated in its electro-chemical and dualistic form by its author in 1817, received a further development at his hands in 1834 after the discovery of the benzoyl-radical by Liebig and Wöhler. In the same year (1834), however, a discovery was made by Dumas, which was destined profoundly to modify the electro-chemical portion of the theory, and even to overthrow the form of it put forth by Berzelius. Dumas showed that an electro-negative element, such as chlorine, might replace, atom for atom, an electro-positive element like hydrogen, in some cases without much alteration in the character of the compound. This law of substitution has formed a necessary portion of every chemical theory which has been proposed since its discovery, and its importance has increased with the progress of the science.

Chemists have been engaged in determining, by means of decompositions, the molecular architecture, or *constitution* as it is called, of various compounds, natural and artificial, and in verifying by synthesis the correctness of the views thus arrived at.

It was long supposed that an impassable barrier existed between inorganic and organic substances: that the chemist could make the former in his laboratory, while the latter could only be produced in the living bodies of animals or plants,—requiring for their construction not only chemical attractions, but a supposed "vital force." It was not until 1828 that Wöhler broke down this barrier by the synthetic production of urea, and since his time this branch of science in the hands of Hofmann has made great strides.

In connection with the rectification of the atomic weights it may be mentioned that a so called natural system of the elements has been introduced by Mendelejeff (1869), in which the properties of the elements appear as a periodic function of their atomic weights. By the aid of this system it has been possible to predict the properties and atomic weights of undiscovered elements, and in the case of known elements to determine many atomic weights which had not been fixed by any of the usual methods. Several of these predictions have been verified in a remarkable manner. A periodicity in the atomic weights of elements belonging to the same class had been pointed out by Newlands about four years before the publication of Mendelejeff's memoir.

In Mechanical Science the progress has not been less remarkable than in other branches. Indeed to the improvements in mechanics we owe no small part of our advance in practical civilisation, and of the increase of our national prosperity during the last fifty years.

This immense development of mechanical science has been to a great extent a consequence of the new processes which have been adopted in the manufacture of iron, for the following data with reference to which I am indebted to Captain Douglas Galton. About 1830, Neilson introduced the Hot Blast in the smelting of iron. At first a temperature of 600° or 700° Fahrenheit was obtained, but Cowper subsequently applied Siemens' regenerative furnace for heating the blast, chiefly by means of fumes from the black furnace, which were formerly wasted; and the temperature now practically in use is as much as 1400° or even more: the result is a very great economy of fuel and an increase of the output.

Bessemer, by his brilliant discovery, which he first brought before the British Association at Cheltenham in 1856, showed that Iron and Steel could be produced by forcing currents of atmospheric air through fluid pig metal, thus avoiding for the first time the intermediate process of puddling iron, and converting it by cementation into steel. These changes, by which steel can be produced direct from the blast furnace instead of by the more cumbersome processes formerly in use, have been followed by improvements in manipulation of the metal.

The inventions of Cort and others were known long before 1830, but we were then still without the most powerful tool in the hands of the practical metallurgist, viz., Nasmyth's steam hammer.

Steel can be produced as cheaply as iron was formerly; and its substitution for iron as railway material and in shipbuilding, has resulted in increased safety in railway travelling, as well as in economy, from its vastly greater durability.

The introduction of iron, has, moreover, had a vast influence on the works of both the civil and military engineer. Before 1830, Telford had constructed an iron suspension turnpike-road bridge of 560 feet over the Menai Straits; but this bridge was not adapted to the heavy weights of locomotive engines. At the present time, with steel at his command, Mr. Fowler is engaged in carrying out the design for a railway bridge over the Forth, of two spans of 1700 feet each; that is to say, of nearly one-third of a mile in length.

But it is in railroads, steamers, and the electric telegraph, that the progress of mechanical science has most strikingly contributed to the welfare of man. To the latter I have already referred.

As regards railways, the Stockton and Darlington Railway was opened in 1825, but the Liverpool and Manchester Railway, perhaps the first truly passenger line, dates from 1830, while the present mileage of railways is over 200,000 miles, costing nearly 4,000,000,000*l.* sterling. It was not until 1838 that the *Sirius* and *Great Western* first steamed across the Atlantic. The steamer, in fact, is an excellent epitome of the progress of the half-century; the paddle has been superseded by the screw; the compound has replaced the simple engine; wood has given place to iron, and iron in its turn to steel. The saving in dead weight, by this improvement alone, is from 10 to 16 per cent. The speed has been increased from 9 knots to 15, or even more. Lastly, the steam-pressure has been increased from less than 5 lbs. to 70 lbs. per square inch, while the consumption of coal has been brought down from 5 or 6 lbs. per horse-power to less than 2. It is a remarkable fact that not only is our British shipping rapidly on the increase, but it is increasing relatively to that of the rest of the world. In 1860 our tonnage was 5,700,000 against 7,200,000; while it may now be placed as 8,500,000 against 8,200,000; so that considerably more than half the whole shipping of the world belongs to this country.

If I say little with reference to Economic Science and Statistics, it is because time, not materials, are wanting.

I scarcely think that in the present state of the question I can be accused of wandering into politics if I observe that the establishment of the doctrine of free trade as a scientific truth falls within the period under review.

In Education some progress has been made towards a more rational system. When I was at a public school, neither science, modern languages, nor arithmetic formed any part of the school system. This is now happily changed. Much, however, still remains to be done. Too little time is still devoted to French and German, and it is much to be regretted that even in some of our best schools they are taught as dead languages. Lastly, with few exceptions, only one or two hours on an average are devoted to science. We have, I am sure, none of us any desire to exclude, or discourage, literature. What we ask is that, say, six hours a week each should be devoted to mathematics, modern languages, and science, an arrangement which would still leave twenty hours for Latin and Greek. I admit the difficulties which schoolmasters have to contend with; nevertheless, when we consider what science has done and is doing for us, we cannot but consider that our present system of education is, in the words of the Duke of Devonshire's Commission, little less than a national misfortune.

In Agriculture the changes which have occurred in the period since 1831 have been immense. The last half century has witnessed the introduction of the modern system of subsoil drainage founded on the experiments of Smith of Deanston. The thrashing and drilling machines were the most advanced forms of machinery in use in 1831. Since then there have been introduced the steam-plough; the mowing-machine; the reaping-machine, which not only cuts the corn but binds it into sheaves; while the steam-engine thrashes out the grain and builds the ricks. Science has thus greatly reduced the actual cost of labour, and yet it has increased the wages of the labourer.

It was to the British Association, at Glasgow in 1841, that Baron Liebig first communicated his work "On the Application of Chemistry to Vegetable Physiology," while we have also from time to time received accounts of the persevering and important experiments which Mr. Lawes, with the assistance of Dr. Gilbert, has now carried on for more than forty years at Rothamsted, and which have given so great an impulse to agriculture by directing attention to the principles of cropping, and by leading to the more philosophical application of manures.

I feel that in quitting Section F so soon, I owe an apology to our fellow-workers in that branch of science, but I doubt not that my shortcomings will be more than made up for by the address of their excellent President, Mr. Grant-Duff, whose appointment to the governorship of Madras, while occasioning so sad a loss to his friends, will unquestionably prove a great advantage to India, and materially conduce to the progress of science in that country.

Moreover, several other subjects of much importance, which might have been referred to in connection with these latter Sections, I have already dealt with under their more purely scientific aspect.

Indeed, one very marked feature in modern discovery is the manner in which distinct branches of science have thrown, and are throwing, light on one another. Thus the study of geographical distribution of living beings, to the knowledge of which our late general secretary, Mr. Sclater, has so greatly contributed, has done much to illustrate ancient geography. The existence of high northern forms in the Pyrenees and Alps points to the existence of a period of cold when Arctic species occupied the whole of habitable Europe. Wallace's line—as it has been justly named after that distinguished naturalist—points to the very ancient separation between the Malayan and Australian regions; and the study of corals has thrown light upon the nature and significance of atolls and barrier-reefs.

In studying the antiquity of man, the archæologist has to invoke the aid of the chemist, the geologist, the physicist and the mathematician. The recent progress in astronomy is greatly due to physics and chemistry. In geology the composition of rocks is a question of chemistry; the determination of the boundaries of the different formations falls within the limits of geography; while palæontology is the biology of the past.

And now I must conclude. I fear I ought to apologise to you for keeping you so long, but still more strongly do I wish to express my regret that there are almost innumerable researches of great interest and importance which fall within the last fifty years (many even among those with which our Association has been connected) to which I have found it impossible to refer. Such for instance are, in biology alone, Owen's memorable report on the homologies of the vertebrate skeleton, Carpenter's laborious researches on the microscopic structure of shells, the reports on marine zoology by Allman, Forbes, Jeffreys, Spence Bate, Norman, and others; on Kent's Cavern by Pengelly; those by Duncan on corals; Woodward on crustaceæ; Carruthers, Williamson, and others on fossil botany, and many more. Indeed no one who has not had occasion to study the progress of science throughout its various departments can have any idea how enormous—how unprecedented—the advance has been.

Though it is difficult, indeed impossible, to measure exactly the extent of the influence exercised by this Association, no one can doubt that it has been very considerable. For my own part, I must acknowledge with gratitude how much the interest of my life has been enhanced by the stimulus of our meetings, by the lectures and memoirs to which I have had the advantage of listening, and above all, by the many friendships which I owe to this Association.

Summing up the principal results which have been attained in the last half-century we may mention (over and above the accumulation of facts) the theory of evolution, the antiquity of man, and the far greater antiquity of the world itself; the correlation of physical forces and the conservation of energy; spectrum analysis and its application to celestial physics; the higher algebra and the modern geometry; lastly, the innumerable applications of science to practical life—as, for instance, in photography, the locomotive engine, the electric telegraph, the spectroscope, and most recently the electric light and the telephone.

To science, again, we owe the idea of progress. The ancients, says Bagehot, "had no conception of progress; they did not so much as reject the idea; they did not even entertain it." It is not, I think, now going too far to say that the true test of the civilisation of a nation must be measured by its progress in science. It is often said, however, that great and unexpected as the recent discoveries have been, there are certain ultimate problems which must ever remain unsolved. For my part I would prefer to abstain from laying down any such limitations. When Park asked the Arabs what became of the sun at night, and whether the sun was always the same, or new each day, they replied that such a question was childish, and entirely beyond the reach of human investigation. I have already mentioned that, even as lately as 1842, so high an authority as Comte treated as obviously impossible and hopeless any attempt to determine the chemical composition of the heavenly bodies. Doubtless there are questions, the solution of which we do not as yet see our way even to attempt; nevertheless the experience of the past warns us not to limit the possibilities of the future.

But however this may be, though the progress made has been so rapid, and though no similar period in the world's history has been nearly so prolific of great results, yet, on the other hand, the prospects of the future were never more encouraging. We must not, indeed, shut our eyes to the possibility of failure; the temptation to military ambition; the tendency to over-interference by the State; the spirit of anarchy and socialism; these and other elements of danger may mar the fair prospects of the future. That they will succeed, however, in doing so, I cannot believe. I cannot but feel confident hope that fifty years hence, when perhaps the city of York may renew its hospitable invitation, my successor in this chair—more competent, I trust, than I have been to do justice to so grand a theme—will have to record a series of discoveries even more unexpected and more brilliant than those which I have, I fear so imperfectly, attempted to bring before you this evening. For one great lesson which science teaches is, how little we yet know, and how much we have still to learn.

SECTION B

CHEMICAL SCIENCE

Opening Address by Prof. A. W. Williamson, Ph.D., LL.D., F.R.S., V.P.C.S., President of the Section

On the Growth of the Atomic Theory

It has been thought desirable that on the occasion of this half-centenary celebration of the foundation of this great Association, some notice should be presented to the members of what has been doing in the respective branches of science during the period of our activity; and I have, accordingly, traced out for your consideration a very imperfect sketch of the theories which guided chemical inquiry at the beginning of that period, and of the leading changes which have been wrought in them by fifty years' work.

There is perhaps hardly any branch of science which during the last fifty years has made such great and steady progress as chemistry. Let any one compare recent dictionaries of the science (including the bulky supplements, which contain a record of the chief discoveries made while the body of the work was being compiled) with a treatise of chemistry fifty years old. Let him compare a published record of one year's progress of the science fifty years ago with one of modern date. Let him compare, as far as may be possible, the number of men who formerly devoted their whole time and energy to the advancement of chemistry, or who were engaged in industrial pursuits involving a knowledge of the science, with the corresponding number nowadays. Let him count up the services which chemistry had rendered to common life at the commencement of the epoch with those which it has now to show.

Everywhere he will see marvellous evidences of increasing growth. But if he be a reflecting man, he will not be satisfied with wondering at results: he will endeavour to trace them to

their causes, and to discover the guiding principles which have brought them about: he will try to derive, from a knowledge of those guiding principles, a perception of the means by which such progress can best be continued and extended—how it can be most effectively directed to the benefit of his fellow-men.

It is on this aspect of the question that I propose to address you to-day.

The process of scientific investigation includes a great variety of operations, which may be considered under three headings, mental, sensual, and physical. We think, we observe, and we work with our hands. In planning a new experiment we call to mind what is known of the phenomena in question, and form an opinion as to what is likely to happen under conditions somewhat different from those which existed in previous experiments. We regulate by careful observations the necessary manual operations, so as to obtain with accuracy the desired conditions for the new experiment, and we observe attentively the changes which take place in the course of that experiment. The result of such observations is sometimes in accordance with our anticipation, but very frequently at variance with it. If it accords with our anticipation, we put on record the extension which it has given to the application of the general theory on which that anticipation was founded. But if the result is not what we expected, we carefully and critically revise the reasoning which had led us to expect a particular result, and often repeat the same experiment with greater care, or some modification of it.

Materials for a new theory are gained when logically faultless reasoning, checked by accurate observations, have led to results which could not have been foreseen by the aid of any previous theory. When a theory has thus gained a footing in science, it serves as a guide in further work. It guides us in arranging known facts. It guides us to the discovery of new facts. Sometimes it does these things for a short time only, and is then superseded by some more general theory derived from a wider and more comprehensive view of the facts.

There is, perhaps, nowhere so severe and rigorous a test of the truth of an idea as that which is afforded by its use in any accurate department of experimental science; and it is worth while, on philosophical grounds, to consider briefly the conditions of growth of the chief chemical theories which have withstood this ordeal and proved themselves to be trustworthy guides in experimental science.

Now as far as I know them, the general theories which have played the chief part in the development of chemistry are mere condensed statements of fact.

Every thoughtful man of science has doubtless indulged in speculations to find the cause of facts which are as yet unexplained; has imagined some fundamental condition or property of matter which might cause it to produce effects such as are witnessed. It is to be hoped that the time may be far distant when men of science will confine their thoughts within the range of ideas which are proved to be true. But it is most important that they should not confuse such hypothetical speculations with theories which have received experimental verification, and that while employing any theory they should not lose sight of the limits within which it has been proved to be correct, beyond which it can only be used as an hypothesis.

The foundation of the science of chemistry was laid by the discovery of chemical elements; those distinct varieties of matter which we can neither produce nor destroy. Chemical science treats of those changes of property in matter which can be represented as due to changes of combination of elementary atoms. It knows nothing of the production or destruction of those elementary atoms. Speculations respecting their ultimate form or structure will have found a place in the science as soon as such speculations have helped to arrange the facts which are known, and to discover new chemical facts.

At the commencement of our epoch chemists had classified elements according to their electro-chemical properties. Chemical analysis had established the fact that a good many compounds could be represented as consisting of elementary atoms of two kinds combined in small number. Thus carbonic oxide and carbonic acid had been found to possess respectively a composition which could be represented (adopting our present atomic symbols) by the formulæ CO and CO_2, water by the formula H_2O, marsh gas CH_4, olefiant gas CH_2. The oxides and acids of nitrogen were represented by formulæ corresponding empirically to those which we now adopt. So also ammonia and hydric chloride had their present formulæ. Sulphurous and sulphuric acid had the respective formulæ SO_2 and SO_3. Phosphorus and phosphoric acid had the formulæ P_2O_3 and P_2O_5. Baryta and the oxides of iron had the formulæ BaO, FeO, Fe_2O_3.

Such primary compounds were classified upon the same principle which served for the classification of the elements themselves, into electro-positive or basylous and electro-negative or chlorous compounds, and the smallest quantity of each of them, which consistently with an atomic representation of the results of analysis, was deemed capable of existing, was called an atom of that compound.

Very simple compounds possessed of prominent characteristics and distinct reactions had first been isolated and identified. They were found to contain their constituent elements in proportions easily recognisable as multiples of atomic weights. But such simple compounds are rare exceptions among mineral and organic materials, and if the atomic theory could have gone no further than to guide us to an understanding of these few simple compounds, it must soon have given place to some more fundamental conception. It is moreover worthy of notice that in this its most elementary form the atomic theory was not the only conceivable interpretation of the proportions of combination between elements. Those proportions could be as consistently represented by fractions as by integral multiples. Thus, instead of representing carbonic acid as containing twice as much oxygen as is contained in carbonic oxide, we might have represented it as containing the same quantity of oxygen combined with half as much carbon, and using for the moment atomic symbols for a non-atomic theory, we might have written carbonic acid thus $C\frac{}{2}O$. Or we might represent them both by percentage numbers.

It was so simple and natural to adopt the atomic hypothesis, and to represent compounds as built up of atoms, that chemists seem to have paid little attention to any other mode of representing the proportions of combination. They assumed that the variable proportions of elements, which were observed in compounds, were due to the various numbers of elementary atoms respectively aggregated together in each compound. They perceived that the existence of elementary atoms involved the existence of compound atoms, or molecules, as we now call them, and accordingly they represented each known compound of two elements by a molecular formula as simple as possible, consistently with the view of its atomic constitution. Many of these molecules, such as those of the acids, were found to be capable of combining with others of the other class, forming salts, and those combinations were found to take place in proportions corresponding to the weights of the respective molecules, or to very simple multiples of those weights, and the secondary compounds or salts thus formed combined (if at all) in proportions corresponding to simple multiples of their molecular weights. The dualistic representation of the constitution of salts served to represent the results of their analysis consistently with the atomic theory, and a vast number of fundamental facts were collected and arranged by the aid of the dualistic theory of combination.

The actual numbers obtained by analysis of any particular compound exhibited sometimes a very near approximation to those required by an atomatic formula of its composition. Sometimes they differed considerably from those required by theory; but it was always found that the more pure in substance and the more accurate the analytical operations, the more nearly did the result agree with some atomic formula of the substance.

The compound atoms were units which had grown out of the atomic theory. Each of them was the smallest quantity of a compound, which (consistently with the results of analysis) could be represented as built dualistically of its constituent atoms.

Chemical combination was viewed as a process of juxtaposition, of simple or compound atoms, little account being taken of the disturbance of the previous arrangement of those compound atoms. It was when a constitution, similar to that attributed to salts, was imagined for other compounds not saline in their character, that the dualistic theory broke down. Thus chlorocarbonic acid was represented as a compound of carbonic acid with carbonic chloride, and was accordingly designated as carbonate of carbonic chloride, while the formula was made to contain the formulæ of those bodies. Chlorosulphuric acid and chlorochromic acid were in like manner represented as compounds of sulphuric and chromic acid respectively with imaginary hexachlorides.

Careful investigations of the reactions in which chlorocarbonic acid takes part showed, however, that in each of them it behaves

as a compound containing only two atoms of chlorine. It was found that the commonest and best-known carbonates and sulphates have a fundamentally similar constitution. Thus potassic carbonate may be represented as a compound in which the two atoms of chlorine in phosgene are replaced by two atoms of the radical O K; and oil of vitriol, as a compound of two atoms of hydroxyl with the same group, SO_2, which in chlorosulphuric acid is combined with two atoms of chlorine. Chlorochromic acid has not been examined to as great an extent as the above compounds, but all we know of it points clearly to its having molecular constitution similar to that of chlorosulphuric acid, viz. $Cl_2 Cr O_2$, for not only do their vapour-densities agree, but the chromates in their constitution and crystalline forms exhibit a clear analogy to the sulphates.

Moreover, the simpler molecular formulæ, which a fuller knowledge of their chemical behaviour suggested for these bodies, were found in all cases to agree with the volume belonging to the molecule of every pure substance known in the state of vapour.

A difficulty of another kind had been foreseen by the great founder of the dualistic system, and it was by the investigations in organic chemistry that it assumed serious proportions.

Carbon compounds were discovered possessing definite and specific properties, and presenting the characteristics of pure substances, but of which the results of analysis did not agree with any simple proportion between the numbers of their constituent atoms. Their empirical composition could not be decided by the aid of the so-called law of multiple proportions, for two or more atomic formulæ required percentages of the constituents differing so little from one another that analysis could not decide which was the true one.

In order to select the true molecular formulæ of such complex substances from among those which approached most nearly to the results of ultimate analysis, and to determine with certainty their empirical composition, it was necessary to find other methods for the determination of molecular weights. It was necessary to study the various properties of compounds of known composition, and of others which could be prepared in a state of purity; to determine the vapour densities and rates of diffusion of those which could be obtained in the gaseous state without decomposition; to determine boiling points and melting points; to examine crystalline forms of pure compounds and of mixtures; to determine solubilities and densities of solids and of liquids; but above all it was necessary to collect fuller and more accurate knowledge of the chemical changes which take place in the mutual reaction of molecules.

A vast amount of accurate and careful work of these kinds has been done, and has been subjected to rigid and often hostile scrutiny during the various steps of its progress. We now know that compound atoms, or molecules as we call them, which can be identified by their geometrical, mechanical, and other properties, are the same as the compound atoms indicated by the most comprehensive chemical evidences of composition and reactions. The molecular constitution of matter was predicted implicitly by the atomic theory of the constitution of the elements; and, wherever the physical properties of the molecules are such as afford any basis for the determination of their relative weights, such results agree with those derived from purely chemical considerations guided by the atomic theory.

Our knowledge of molecules is as yet in its infancy. Even among the commonest elements and compounds we know the molecular weights of very few, but what we do know of them proves that the idea of compound atoms invented by chemists to explain the elementary facts of chemical action is, as far as it goes, a true representation of what exists in nature.

Many of the molecules thus proved to exist were the same as those suggested under the dualistic system; but many were proved, by the more accurate and extensive knowledge of their reactions and properties, to have a different weight from that which had been at first attributed to them, yet always consistent with the fundamental requirements of the atomic theory. Thus H_2O, CO, CO_2, CH_4, SO_2, SO_3, CaO, FeO, Fe_2O_3, are the formulæ still used to denote the molecules of the respective compounds, though the last three ought probably to be represented by some multiple. On the other hand, the molecule of olefiant gas is now represented by the formula C_2H_4, instead of CH_2. The chloracetate is $C_2Cl_3HO_2$, instead of C_2Cl_6, C_2O_3, H_2O. The molecule of benzoil chloride is C_7H_5OCl, instead of one corresponding to $(C_7H_5)_2O_2$, $C_7H_5Cl_3$, and chlorosulphuric acid is Cl_2SO_2, instead of $2SO_3$, SCl_6.

In proportion as chemists came to know more of the constitution of molecules, and to study chemical reactions from the point of view of the changes which they bring about in the constitution of molecules, did the idea of substitution come to be more and more used in the place of that of mere additive combination. A vast number of processes of chemical combination, which had been considered as consisting of direct combination, were found to be processes of double decomposition.

One of the most important facts which was brought to light by the careful examination of the composition of salts and organic bodies, aided by the molecular method of representing their constitution, was that hydrogen is chemically one of the metals, and that the compounds formed by the combination of water with acids are analogous to other salts of those acids; while compounds of hydrogen with elements or radicals like chlorine are salts, analogous in their constitution to other chlorides, &c.

The molecular or unitary mode of viewing the constitution of each substance affords more *true* as well as more simple records of the facts observed in chemical reactions than could be obtained in the dualistic systems. A salt such as hydric sulphate used to be considered as containing sulphuric acid and water, and represented by a formula such as SO_3, H_2O, implying the presence in it of both the substances from which it was known to be formed.

When two elements combined, their product was considered and described as containing the elementary atoms which had served to form it, and it was consistent with this habit to represent a product which had been formed by the combination of two compound molecules as containing those molecules.

But the main business of chemical investigation is to observe accurately the changes of composition which take place in the reactions of known substances, with a view of discovering the atomic changes to which they are due.

The compound formed by the combination of sulphuric acid and water differs in many physical and chemical properties from both of those bodies. Its name and its atomic formula serve to denote the aggregate of properties which are known to belong to it, whereas the dualistic formula, SO_3, H_2O, served to recall the properties of the acid and base from which it was formed, rather than those of the compound itself.

Elementary chemical reactions which according to the binary mode of viewing compounds were supposed to consist of dualistic processes involving sometimes the assumption of forces (like predisposing affinity) of a purely metaphysical character, were now explained as consisting of atomic displacements, or interchanges of a kind well known to be of common occurrence. Thus the evolution of hydrogen by the action of zinc or aqueous hydric sulphate was supposed to be the result of a decomposition of water by the metal, such decomposition being induced by the presence of the acid (SO_3), which exerted a predisposing affinity for the zinc oxide. Our present explanation is a simple statement of the fact, that under the conditions described, zinc displaces hydrogen from its sulphate.

The recognition and study of the metallic functions of hydrogen enabled chemists to obtain far clearer and simpler views of the constitution of salts, and to observe the differences of property which are produced in them by the replacement of one element by another. It enabled us to see more and more clearly the characteristic functions of each element, by comparing the constitution and properties of salts containing it with those of the corresponding salts containing other elements.

Thus in the dualistic system we had for the three common phosphates, PO_4Na_3, PO_4Na_2H, PO_4NaH_2, molecular formulæ in which sodium was represented with twice as great an atomic weight as that which we attribute to it, and which in our atomic weights may be thus represented, viz. P_2O_5, $3Na_2O$; P_2O_5, $2Na$, O; P_2O_5, Na_2O. In like manner we had such a formula as P_2O_3, $2Na_2O$ (for the phosphite PO_3Na_2H), and for the hypophosphite PO_2NaH_2 we had a formula corresponding to P_2O, Na_2O.

Determinations of water of crystallisation and of chemically combined water proved that many of the compounds assumed on the dualistic system to exist are either not obtainable or have different properties and a different constitution from those which have been described. Thus we now know that the salts PO_4Na_2H, PO_4NaH_2, PO_3Na_2H, and PO_2NaH_2 cannot be deprived of the elements of water without undergoing a fundamental change of composition and of properties.

The atomic weights of the alkali metals and of silver were

found to be half of those of the dualistic system, and an atom of one of these metals, in common double decompositions between their salts and hydrogen-salts, changes place with one atom of hydrogen.

Many products of the combination of known molecules were found to be formed by processes of double decomposition, so that each molecule of such products is built up partly of atoms derived from one of the materials, partly of atoms from the other. Thus potassic hydrate is formed by the combination of a molecule of potash with one of water. Yet each molecule of the hydrate is built up of half a molecule of potash and half a molecule of water.

The study of organic compounds played an important part in the improvement of our processes of reasoning. Many of their molecules having a very complex structure were found to undergo in most of their reactions very simple changes, of the same kind as those which mineral compounds undergo. Most of the elements of each organic molecule remained combined together with functions analogous to those of hydrogen or chlorine.

The theory of radicals which had been suggested by the reactions of ammonia-salts and of cyanides was largely extended in organic chemistry.

Many families of organic compounds were discovered, in each of which the members are connected by close analogy of constitution and of properties. Each of these families forms what is called a homologous series, each term of the series being a compound of which the molecule contains one atom of carbon and two atoms of hydrogen more than the previous term.

Thus a series of compounds was proved to have reactions similar to those of common alcohol, and molecular weights ranging from 32 to 438. The lower terms of the series are distinguished from one another by differences of boiling points approximately proportional to the number of atoms of carbon and hydrogen by which they differ from one another; whilst the higher terms undergo decomposition at the higher temperatures required for their evaporation, and are distinguished from one another by differences of melting points, that of the alcohol $C_{30}H_{62}O$ being about 85° C. In their constitution these alcohols were found to be analogous to the alkaline hydrates.

In like manner various other series of alcohols were discovered corresponding respectively in their constitutions to other classes of metallic hydrates. Series were also found of which the members present analogies of reaction with monobasic, bibasic, tribasic hydrogen salts respectively.

These and many other such discoveries were made under the guidance of the atomic theory, developed to the point of systematically recognising and studying the mutual reaction of molecules.

One of the most remarkable and important extensions which our knowledge of molecules has undergone consisted in the discovery that various elements in what we are accustomed to consider the free state, really consist of molecules containing like atoms combined with one another.

Thus chemists adopt the formulæ O_2, H_2, Cl_2, P_4, J_2, As_4, to denote molecules of the respective elements, and we have for these molecular formulæ evidences of the same kinds as those which serve to establish the molecular formulæ ClH, H_2O, NH_3, &c. In all the best-known reactions in which chlorine or hydrogen are either taken up or evolved we find that those elements behave as chemical compounds of two like atoms; and, moreover, their molecules, as determined from a study of their reactions, have the same volume as that of every compound molecule proved to evaporate without decomposition.

With this knowledge of the molecular constitution of hydrogen and of chlorine gases, we come to regard the direct formation of hydric chloride as due to a process of double decomposition between two molecules, like the reaction of chlorine on an equal volume of marsh gas.

Many other reactions, such as the evolution of hydrogen by the action of zinc on a hydrogen salt, the liberation of chlorine and nitrogen on the explosive decomposition of their compound, the direct combination of oxygen and hydrogen, we may expect to be able to resolve into mere processes of double decomposition.

The earliest determinations of combining proportions were made with salts (hydrogen salts and others) which undergo double decomposition by mutual contact, and the term equivalent was subsequently introduced to indicate the proportional weights of analogous substances found to be of equal value in their chemical effects. Tables of equivalent weights of acids consisted of numbers standing to one another in the same proportions as the weights of the respective substances found to be of equal value in neutralising a fixed quantity of a particular base; and in like manner tables of the equivalent weights of bases recorded the proportions by weight in which certain bases might replace one another in the neutralisation of a particular quantity of a given acid. Similar determinations have been tabulated of the so-called equivalent weights of elements. Under the dualistic system chemists paid little attention to the essential difference between atomic weights and equivalent weights; and some were of opinion that the facts of chemistry might be represented as consistently from the point of view of equivalence as from that of atoms, and that the idea of atoms (which they considered to be hypothetical) might be dispensed with.

In the system of atomic weights employed under that system, two atoms of hydrogen were generally represented as reacting together, and the symbol of the double atom was marked thus, H. The alkali metals and silver were represented as having atomic weights twice as great as those which we now adopt, and equivalent to those of the magnesian metals and of oxygen. In a great number of the common reactions of these elements the atomic symbols were consistently used as equivalent symbols. But those who professed to dispense with the atomic theory used atomic symbols, even in cases where they did not represent equivalent weights. Thus nitrogen was always represented by its atomic symbol, and the composition and reactions of nitrogen compounds were always studied and represented in accordance with the atomic theory, using various multiple proportions of what they were still pleased to call equivalent weights, using molecular weights, and various other ideas which formed part of the atomic theory, and which had no known connection with the notion of fixed equivalence. If, however, it be true that all chemical compounds consist of elementary atoms, and that the explanation of chemical reactions consists in stating more and more precisely the changes of combination between the constituent atoms of the reacting molecules; equivalence could only be said to exist between a like number of atoms when they were known to have similar functions. It became necessary to study the relation of equivalence between elementary atoms, instead of studying them from the point of view of elements divisible in any proportion.

It is worth while noticing the general process by which this intellectual change was brought about; for there is a good deal yet to be done in the matter, and our future progress may be guided by experience gained in the past.

It was essentially one-sided. One consideration was brought into very prominent relief, and it threw a marvellous light on the matter. It gave us a clear view of the natural order among elements; but, like every other strong light, it fell on one side only.

The equality of vapour-volumes had been used with great advantage in conjunction with chemical reactions and other evidence as a characteristic of molecules, and the attention of chemists was greatly arrested by the consideration of four typical compounds, which upon the concurrent evidence of very extensive chemical examination and equality of vapour-volumes were known to have respectively a composition corresponding to the formulæ ClH, OH_2, NH_3, CH_4.

It was known that the atom of oxygen in water can be replaced by chlorine, but that two atoms of chlorine are needed for the purpose. The atom of nitrogen in ammonia requires three atoms of chlorine to replace it, whilst in marsh gas the atom of carbon is replaceable by four atoms of chlorine. Other elements were studied from the point of view of their respective resemblance to these, and arranged in classes, each of which consisted of atoms equivalent to one another. Thus chlorine, bromine, iodine, fluorine, hydrogen, potassium, sodium, lithium, silver, &c., constituted a class of atoms of equal value, and were called monads. Oxygen, sulphur, selenium, tellurium, calcium, strontium, barium, magnesium, zinc, cadmium, mercury, lead, copper, &c., were classed together as dyads, having equal value amongst themselves, but double the atomic value of the members of the first class. So nitrogen, phosphorus, arsenic, antimony, bismuth, with boron, and some other elements, were considered as forming a class of atoms each of which has three times the value of the monads. The class of tetrads contained carbon, silicon, tin, platinum, &c.

Many apparent exceptions to these atomic values were satisfactorily explained as due to the partial combination of like

atoms with one another. Thus in the vast majority of hydrocarbons, such as C_2H_6, C_2H_4, C_2H_2, &c., the atoms of carbon do not appear to be tetravalent, inasmuch as each of the molecules contains less than four atoms of hydrogen to every one atom of carbon. It was well known, however, that polyvalent atoms can combine partly with one element, partly with another, and also that like atoms can combine with one another. Why then should not two tetravalent atoms like carbon combine respectively with three atoms of a monad, and also combine with one another? The compound must be a single molecule with the properties known to belong to methyle C_2H_6. Again, if this molecule were deprived of two of its atoms of hydrogen, each of the atoms of carbon must combine further with the other atom of carbon forming H_2CCH_2; and a further step in this same direction would give us acetylene HCCH, in which each atom of carbon is combined with the other to the extent of three quarters of its value, and with one atom of hydrogen. An extension of this reasoning led to the discovery of long chains of atoms of carbon, each atom forming a link, and each of them (short of the ends) being combined with two other atoms of carbon, while its saturation is completed by hydrogen.

Similar partial combinations of like atoms with one another were recognised in many other classes of compounds, and there is strong reason to expect that the application of the principle will be far more widely extended in proportion as our knowledge of the silicates and other complex classes of compounds becomes somewhat definite.

This incorporation of the doctrine of equivalence into the atomic theory by the division of the elements into classes consisting respectively of equivalent atoms, was probably one of the most important general steps as yet made in the development of the atomic theory. It was seen to correspond in so clear and striking a manner with a vast number of well-known properties and reactions of compounds as to deserve and acquire the confident trust of chemists. But, as often happens in such cases, this confidence in the result carried many of them too far. It led them to assume that atomic values in all other chemical compounds must be always the same as in the compounds under consideration. They saw that they had got hold of the truth, and they thought it was the whole truth. For instance, one most distinguished chemist assumed that each elementary atom has only one value in its compounds; that the atom of nitrogen has always the value three, as in ammonia and its products of substitution, and that in sal ammoniac the atom of nitrogen is chemically combined only with three atoms of hydrogen, whilst the molecule of ammonia is in a state of molecular combination with hydric chloride. Another most distinguished chemist admitted that nitrogen and phosphorus have two atomic values, but not more than two. He held that the respective combining powers are always satisfied by the same number of atoms, no matter what the character of the uniting atoms may be.

With respect to these views it may be noticed that the assumption of combination between molecules as due to some other force than that which binds together the constituents of each molecule—in fact the assumption of molecular combination as an unknown something different from chemical combination, is open to even more grave objections than those which led us to abandon the dualistic system.

To represent a molecule of sal ammoniac as a compound containing two molecules, each one built up by the chemical combination of the constituent atoms, and the two united together by some other force called molecular, was hardly a step in advance of the view which represented it as containing two molecules united together by the same kind of force as that which holds together the atoms in each of the constituent molecules.

The other form of the theory of atomicity as an inherent property of each atom enabling it to combine with an equal number of other atoms, whatever the character of those other atoms may be, seems difficult to reconcile with such facts as the following:—An atom of nitrogen is not known to combine with more than three atoms of hydrogen alone, or of substances like hydrogen, but it forms stable compounds with five atoms (as in the ammonia salts), when four of them are basylous and one of them is chlorous. An atom of sulphur is not known to combine with more than two atoms of hydrogen alone, but it forms stable compounds with four atoms, if three of them are like hydrogen, while the fourth is chlorous. Instances like these are plentiful, and they lead us to look to the chemical characters of the atoms bound together in one molecule as a fundamental condition of the atomic value of the element which binds them together.

Theoretical limitations of natural forces are very difficult of proof, and it is well to be slow and cautious in adopting any such limitation.

A careful consideration of the facts of the case has led me not only to doubt the validity of the supposed limits of atomic value, but to doubt whether we have grounds for assigning any limits whatever to such values.

Atomic values appear to me to be in their very nature variable quantities, and I venture to think that chemistry will be greatly advanced by a full and careful study of the conditions of variation of atomic values.

Two conditions of change of atomic value are particularly worthy of notice:—

I. Temperature.

II. The chemical character of the uniting atoms.

Atomic values increase with fall of temperature, and diminish with rise of temperature. An atom which is combined with as many basylous monads as it can take up by themselves, will take up chlorous monads, or both chlorous and basylous, and reciprocally.

In illustration of the diminution of atomic values with rise of temperature, I may adduce the following well-known reactions: Sal ammoniac containing nitrogen combined with five monads breaks up at a high temperature into ammonia and hydric chloride; and in like manner other ammonia salts decompose by heat forming ammonia or an amide, with trivalent nitrogen. The highest chlorides of phosphorus and of antimony are decomposed by heat into free chlorine and the lower chloride. Potassic fluosilicate is decomposed by heat into silicic and potassic fluorides; and carbonic acid breaks up at high temperatures into a mixture of carbonic oxide and oxygen.

Amongst illustrations of the greater atomic values which elements assume by combining with both chlorous and basylous atoms than with atoms of the one kind only, we may take the following cases: platinum is a metal of which the atom has been supposed to be always tetravalent, because it has not been found capable of combining with more than four atoms of chlorine. The common solution formed by aqua regia contains the compound H_2PtCl_6, a perfectly definite and crystallisable hydrogen salt. Chemists are constantly making and using the potassium and ammonium salts, &c., corresponding to it, yet they conceal from themselves the fact that the atom of platinum is directly combined with eight monads by calling the compounds double salts. The atom of silicon in the silico-fluorides such as H_2SiF_6, or K_2SiF_6, is combined with twice as many monads as it can take up of one kind; so boron in the crystalline salt $NaBF_4$ has a higher atomic value than in its fluoride, owing to the presence of the atom of sodium.

In like manner the atom of gold in the well-known salt $NaAuCl_4$, has a higher value than it can assume with chlorine alone.

Sulphur, of which the atom does not combine with more than 2 atoms of hydrogen, forms with 3 atoms of methyle, or ethyle, and 1 atom of iodine, or chlorine, &c., the well-known compounds like $JSMe_3$; and iodine, which is considered a monad, forms the crystalline and stable periodate $OJ(OH)_5$ and the various metallic derivatives, such as

$OJ\,ONa$	$OJ\,(ONa)_2$	$OJ\,(OAg)_5$
$(OH)_4$	$(OH)_3$	

The crystalline compound of the perchlorate with water ($HClO_4 2H_2O$) has probably a similar constitution. Chemical journals abound with descriptions of definite and well-characterised compounds, which have, like the above, been put aside by the atomicity theory, as mere molecular compounds. The following formulæ are taken almost at random, in illustration of the generality of atomic values far beyond those acknowledged by the theory of atomicity.

$JPCl_6$	K_2FeF_4	K_2SnCl_6
$KAsF_6$	$2(K_2FeCl_5)$	$KHgJ_3$
K_2AsF_7	$2(K_2FeF_6)$	$K_2HgJ_44H_2O$
$KSbF_6$	K_2CuCl_4	$KHgCl_3$
K_2SbCl_5	K_2CuF_4	K_2HgCl_4
K_2SbF_7	$KMgCl_3$	
K_2BiCl_5	K_2MgBr_4	
K_2AgJ_3		

I have for convenience written in the middle of each of these

formulæ the symbol of the atom which I assume to act as connecting element. If we consider the atomic values usually found in these elements, together with those represented by the above list, we see that their atomic values vary according to the numbers given in a line with them respectively in the following table. It has yet to be proved that the atom of platinum is tetravalent in any known compound, for there is no sufficient evidence to show that platinic chloride has a molecular weight corresponding to the formula $PtCl_4$, instead of one corresponding to Pt_2Cl_8, each atom of platinum being partly combined with the other, partly with chlorine.

Atomic Symbols.	Atomic Values.
C	2, 4
S	2, 4
Pt	4 (?), 8
Si	4, 8
Sn	4, 8
Cu	2, 6
Hg	2, 4, 6
Mg	2, 4, 6
Ag	1, 5
B	3, 5
J	1, 7
N	3, 5
P	3, 5, 7
As	3, 7, 9
Sb	3, 5, 7, 9
Bi	3, 7
Au	3 (?), 5

Not only are there elements of which an atom is found in combination with a greater number of basylous and chlorous monads together than of either kind alone, but there are also elements which are not known to form chemical compounds with hydrogen or potassium alone, and yet which combine with either of them when also combined with chlorine, fluorine, &c. This is illustrated by the following compounds, viz., $HAuCl_4$, H_2PtCl_6, $NaBF_4$, K_2SiF_6, K_2FeF_4, K_2CuCl_4. It is also well known that there are many cases of elements of which an atom cannot combine with as many monads of one kind as of another. For instance an atom of nitrogen or of antimony is only known to be trivalent in combination with hydrogen; but each of them occurs in the form of a pentavalent compound with chlorine. Antimony forms either no compound with five atoms of bromine, or a compound more unstable than the higher chloride.

Many more such instances might easily now be given, and a vast number will doubtless be found when the investigations of chemists are directed to the search for them. I have only given these few by way of illustration of the leading conditions of change of atomic values.

In the course of their investigations of the precise interchanges of atoms which take place between molecules, chemists were frequently led to observe evidences of the order in which the constituent elements are combined; and with the more wide and accurate knowledge of reactions which is now in their possession, they have been enabled to follow up so far the study of the respective state of combination of each atom in a molecule as to arrive at simple and consistent explanations of facts which had previously eluded the grasp of science.

Our knowledge of the order of combination of atoms in a molecule and of the differences between direct and indirect combinations of particular atoms may be said to have originated chiefly in the study of the compounds of nitrogen. Thus it was found that the hydrogen in ammonia differs in many of its chemical functions from hydrogen in hydrocarbons. A base (called methylia) was discovered having a molecular composition corresponding to the empirical formula $(CNH_3)_3$, and this base was found to contain two atoms of hydrogen like those of ammonia, and three atoms like those in hydrocarbons. Its constitution was accordingly represented by a formula describing it as an ammonia, in which one atom of hydrogen is replaced by the monad methyle, or, to be more explicit, as containing two atoms of hydrogen directly combined with nitrogen, and three atoms of hydrogen indirectly combined with that same atom of nitrogen through the intervening atom of carbon. Writing in juxtaposition to one another the symbols of those atoms which are directly combined, we can express the facts by the following formula, viz. H_2NCH_3.

Those marvellous varieties of matter called isomeric compounds found their natural explanation in differences of the respective arrangements of like atoms. Thus two bases were discovered having the same empirical molecular formula C_2NH_7. One of them is made by different reactions from the other, and in its decompositions differs from the other. All these chemical differences between them are found to be due to the fact that one of them (called ethylia) contains two atoms of hydrogen directly combined with the nitrogen, and the monovalent hydrocarbon ethyle in place of the third atom of hydrogen; whilst the other (called dimethylia) contains only one atom of hydrogen combined directly with nitrogen, the carbon of the two atoms of methyle completing the saturation of the trivalent nitrogen, as expressed by the formula $HN(CH_3)_2$.

It was subsequently proved that an atom of oxygen may combine with two like or unlike monads, such monads being indirectly combined with one another through the intervening atom of oxygen. Thus five of the atoms of hydrogen in common alcohol were proved to be in direct combination with the carbon, whilst the other one is indirectly combined with it through the oxygen, as expressed by the formula $HO(C_2H_5)$.

Another compound (called methyl-oxide) was proved to have the same empirical composition, but very different properties and reactions, its constitution being explained by the formula H_3COCH_3.

Again, two compounds of distinct reactions and properties were found to have the same empirical molecular composition, C_2NH_3, and it was clearly proved that in one of them the two atoms of carbon are directly combined thus, $NCCH_3$, whilst in the other they are indirectly combined through the atom of nitrogen $CNCH_3$.

An immense amount of admirable work has been done of late years (especially in Germany) in working out the evidences of the atomic order of complex organic bodies, and in thereby obtaining a command of their reactions.

Evidences of the same kind have been obtained of the atomic arrangement of some few of the simplest inorganic bodies, and it is to be hoped that ere long chemists will recognise the importance of examining the constitution of salts with the aid of the principles established in organic chemistry.

The foundation is already laid by our knowledge of the constitution of such compounds as

$$\begin{matrix} HOH,\ HOK,\ HONH_4,\ HONO_2 \\ HOPbOH,\ HOPbONO_2,\ HOCOK,\ HOSOH \\ \qquad\qquad\qquad\qquad\quad O \qquad\quad O_2 \end{matrix}$$

and there is a strong probability regarding the atomic constitution of many other water compounds, *e.g.*

$$SO_4H_2 + H_2O = OS(OH_2)_4, SO_3H_4 + H_2O = S(OH)_6.$$

Amongst the extensions of our means of examining the physical properties of matter, and thereby discovering new varieties of matter for chemical investigation, spectrum analysis has played an important part, and is no doubt destined to do far more. It has already led chemists to the discovery of several previously unknown elements, and has led to the detection of various known elements in distant masses of which we had previously no chemical knowledge.

Up to this point the growth of the atomic theory will be seen, from the general outline which I have endeavoured to trace, to have consisted mainly in the more and more full and exact identification of each elementary atom, and in the accumulation of more and more varied and accurate evidences of its functions in relation to other atoms. A step was made towards a knowledge of the general relations of atoms to one another by their preliminary classification according to their best-known values.

But a far greater step has been more recently made, one which is evidently destined to lead to most important results.

It was discovered that if we arrange the elements in the empirical order of their respective atomic weights, beginning with hydrogen and proceeding thence step by step to the heaviest atom, we have before us a natural series with periodically recurrent changes in the chemical and physical functions of its members.

Of course the series is imperfect, and exhibits gaps and irregularities; but what view of natural order was complete in its infancy?

Some of the gaps have already been filled up by the discovery of elements possessing the anticipated properties. The generalisation affords a brilliant addition to the previous corroborations of the reality of the units of matter which chemists have discovered.

Chemists have as yet taken but little account of atomic motion;

although the most perfect explanation of a chemical reaction consists of a statement of the atomic interchange which takes place between two molecules; or the change of mutual combination between the atoms in one molecule.

It has, however, been proved that the heat of combination affords a measure of its force; and we know that in giving off heat particles of matter undergo a diminution of velocity of motion. We see, accordingly, that substances capable of exerting great force by their combination are those which can undergo a great diminution of the velocity of their internal motions, and reciprocally.

The force of chemical combination is evidently a function of atomic motion.

It has been shown that the relative velocities of certain atomic interchanges afford a measure of the amount of chemical action between two substances; but a vast amount of work will doubtless be required to develop the atomic theory to the point of explaining the force of chemical action in precise terms of atomic motion.

The general terms of chemistry are mere symbols. Each of them serves to recall a group (usually a very large group) of facts established by observation. The explanation of each term is afforded by a careful study of the facts which it is used to denote; and, accordingly, a chain of evidence involving the use of chemical terms can be fully understood only by chemists accustomed to the consideration of such evidence. The general outline of it may perhaps be to some general thinkers of sufficient interest to attract them to further study of our science.

SECTION C

GEOLOGY

OPENING ADDRESS BY A. C. RAMSAY, LL.D., F.R.S., &c., &c., DIRECTOR-GENERAL OF THE GEOLOGICAL SURVEY, PRESIDENT OF THE SECTION

On the Origin and Progress of the Present State of British Geology, Especially since the first Meeting of the British Association at York in 1831

IN the year 1788 Hutton published his first sketch of his "Theory of the Earth," afterwards extended and explained by Playfair in a manner more popular and perspicuous than is done in Hutton's own writings. In this grand work, Hutton clearly explains that the oldest known strata, like their successors, are derivative, and that as far as *observation* can discover, in all geological time, "we find no vestige of a beginning, and no sign of an end." The complement to this far-seeing observation was at length brought about by William Smith, in his original "Geological Map of the Strata of England and Wales" in 1815, followed, in 1816, by his "Strata Identified by Organised Fossils." This great discovery, for such it was, threw a new light on the history of the earth, proving what had before been unknown, that all the "Secondary" formations, at least from the Lias to the Chalk inclusive, contained each a set of distinctive fossils by which it could be recognised. A law was thus provided for the identification of formations which geographically are often widely separated from each other, not only in England in the case of minor outliers, but also easily applicable to great areas on the neighbouring continent of Europe.

In 1811 the first volume of the *Transactions* of the Geological Society was published, and in 1826-27 there appeared the first volume of the *Proceedings*, the object being to communicate to the Fellows as promptly as possible the *Proceedings* of the Society "during the intervals between the appearance of the several parts of the *Transactions*." The last volume of the *Transactions* contains memoirs read between the years 1845-1856, and only four volumes of the *Proceedings* appeared between the years 1826 and 1845 inclusive, after which the title of the annual volume was changed to that of the "Quarterly Journal of the Geological Society." The Geological Society, to which the science owes so much, was therefore in full action when the British Association was founded in 1831, and the memoirs read before the Society from 1831 to this date may be said to show generally the state of British geology during the last fifty years. To this must be added the powerful influence of the first (1830) and later editions of Lyell's "Principles of Geology," a work which helped to lay the foundations of those researches in Physical Geology which both in earlier and later years have attracted so much attention.

Fifty years ago, in this city, Viscount Milton was president of the first meeting of "The British Association for the Advancement of Science," which he explained had for its chief object "to give a stronger impulse and more systematic direction to scientific inquiry." In his address he pointed out the numbers of Philosophical Societies which had by degrees sprung up in all parts of the kingdom; and the practicability, through the means of the Association, "including all the scientific strength of Great Britain," "to point out the lines in which the direction of science should move."

In that year, 1831, Prof. Sedgwick was president of the Geological Society, and the Geological and Geographical Committee of the British Association recommended that geologists should examine the truth of that part of the theory of Élie de Beaumont, in its application to England, Scotland, and Ireland, which asserts that *the lines of disturbance of the strata assignable to the same age are parallel*; that Prof. Phillips be requested to draw up *a systematic catalogue of all the organised fossils of Great Britain and Ireland*; and that Mr. Robert Stephenson, civil engineer, be requested to prepare a report upon *the waste and extension of the land on the east coast of Britain, and the question of the permanence of the relative level of the sea and land*.

In 1881 it seems strange to us that, in 1831, with William Smith's map of "The Strata of England and Wales, with part Scotland," before them, it should have been considered necessary to institute an inquiry as to the truth of the general parallelism of disturbed strata, which, in a limited area like England, had suffered upheaval at different successive epochs; and we may fancy the internal smile with which Phillips, the nephew of Smith, regarded the needless proposal. The masterpiece of the old land-surveyor and civil engineer remains to this day the foundation of all subsequent geological maps of England and Wales; and *as an unaided effort of practical genius*—for such it was—it seems impossible that it should be surpassed, in spite of all the accuracy and detail which happily modern science has introduced into modern geological maps.

The first paper read at York, in the year 1831, was by Prof. Sedgwick, "On the General Structure of the Lake Mountains of the North of England." This was followed by "Supplementary Observations on the Structure of the Austrian and Bavarian Alps," by the Secretary of the Society, Mr. Murchison, a memoir at that time of the highest value, and still valuable both in a stratigraphical point of view and also for the light which it threw on the nature of the disturbances that originated the Alpine mountains, and their relations in point of date to the far more ancient mountains of Bohemia. In his elaborate address in the same year, on his retiring from the president's chair, he largely expatiates on the parallelism of many of the great lines of disturbance of what were then distinguished as the more ancient *schistose* and *greywacke* mountains, and quotes the authority of Élie de Beaumont for the statement, "that mountain chains elevated at the same period of time have a general parallelism in the bearing of their component strata." On a great scale this undoubtedly holds true, as, for example, in the case of the Scandinavian chain, and the more ancient Palæozoic rocks north of Scotland, Cumberland, and even of great part of Wales. The same holds good with regard to the parallelism of the much more recent mountain ranges of the Apennines, the Alps, the Caucasus, the Atlas, and the Himalayas, all of which strike more or less east and west, and are to a great extent of post-Eocene, and even partly of post-Miocene age. The same, however, is not precisely the case with the Apalachian chain and the Rocky Mountains of North America, the first of which trends N.N.W., and the latter N.N.E. The remarkable chain of the Ural Mountains trends nearly true north and south, and is parallel to no other chain that I know of, unless it be the Andes and the mountains of Japan. It is worthy of notice that the chain of the Ural is of pre-Permian age according to Murchison, while Darwin has shown that the chief upheaval of the Andes took place in post-Cretaceous times.

The Apalachian chain is chiefly of post-Carboniferous date, and the Rocky Mountains have been re-disturbed and re-elevated as late as post-Miocene times.

In the same address Prof. Sedgwick entered an eloquent protest against the broad uniformitarian views so powerfully advocated in the first edition of Lyell's "Principles of Geology" in 1830, in which, throwing aside all discussion concerning cosmogony, he took the world as he found it, and, agreeing with Hutton that geology is in no way concerned with, and not sufficiently

advanced to deal "with questions as to the origin of things," he saw that a great body of new data were required, such as engaged the attention of the Geological Society (founded in 1807), and which, along with other foreign societies and private work, has at length brought geological science to its present high position.

And what is that position? With great and consentient labour, many men, gifted with a knowledge of stratigraphical and palæontological geology, have, so to speak, more or less dissected all the regions of Europe and great part of North America, India, and of our colonies, and in vast areas, sometimes nearly adjoining, and sometimes far distant from each other, the various formations, by help of the fossils they contain, have been correlated in time, often in spite of great differences in their lithological characters. It is easy, for example, to correlate the various formations in countries so near as Great Britain and Ireland, or of the Secondary and Lower Tertiary formations of England and France; and what is more remarkable, it is easy to correlate the Palæozoic formations of Britain and the eastern half of the United States and Canada, even in many of the comparatively minute stratigraphical and lithological subdivisions of the Silurian, Devonian, and Carboniferous formations. The same may be said with regard to some of the Palæozoic formations of India, China, Africa, and Australia, and many of the Secondary and Tertiary deposits have in like manner been identified as having their equivalents in Europe. It is not to be inferred from these coincidences that such deposits were all formed *precisely* at the same time, but taken in connection with their palæontological contents, viewed in the light which Darwin has shown with regard to the life of the globe when considered in their relation to masses of stratified formations, no modern geologist who gives his mind to such subjects would be likely to state, for example, that in any part of the globe Silurian rocks may be equivalents in time to any of our Upper Palæozoic, Mesozoic, or Tertiary formations.

For all the latest details of *genera* and *species* found in the British Palæozoic rocks, from those of St. David's, so well worked out by Dr. Hicks, to the Carboniferous series inclusive, I must refer to the elaborate address of Mr. Etheridge, President of the Geological Society, which he delivered at the last anniversary meeting of that society. It is a work of enormous labour and skill, which could not have been produced by any one who had not a thorough personal knowledge of all the formations of Britain and of their fossil contents.[1]

In connection with such subjects I will not in any way deal with the tempting and important subject of cosmological geology, which in my opinion must go back to times far anterior to the date of the deposition, as common sediments, of the very oldest-known metamorphic strata. Cosmological speculations perhaps may be sound enough with regard to refrigeration, and the first consolidation of the crust of the earth, but all the known tangible rocky formations in the world have no immediate relation to them, and in my opinion the oldest Laurentian rocks were deposited long after the beginning and end of lost and unknown epochs, during which stratified rocks were formed by watery agents in the same way that the Laurentian rocks were deposited, and in which modern formations are being deposited now, and the gneissose structure of the most ancient formations was the result of an action which has at intervals characterised all geological time as late as the Eocene formations in the Alps and elsewhere.

The same kind of chronological reasoning is often applicable to igneous rocks. It was generally the custom, many years ago, to recognise two kinds of igneous rocks, viz., Volcanic and Plutonic, and this classification somewhat modified in details is still applicable, the Plutonic consisting chiefly of granitic rocks and their allies, and which though they have often altered and thrust veins into the adjoining strata, have never, as far as I know, overflowed in the manner of the lavas of modern and ancient volcanoes. Indeed, as far as I recollect, the first quoted examples of ancient volcanoes are those of Miocene age in the districts of Auvergne, the Velais, and the Eifel, and the fact that signs of ordinary volcanic phenomena are found in almost all the larger groups of strata was scarcely suspected. Now, however, we know them to be associated with strata of all or almost all geological ages, from Lower Silurian times down to the present day, if we take the whole world into account. Amongst them, those of Miocene date hold a very prominent place, greatly owing, doubtless, to the comparative perfection of their forms, as, for example, those of the South of France and of the Eifel. Their conical shapes, and numerous extinct craters, afford testimony so plain, that he who runs may read their history. The time when they became extinct would doubtless amaze us by its magnitude, if it could be stated in years, but yet it is comparatively so recent that not all the undying forces of atmospheric degradation have been able to obliterate their individual origin.

It is, however, generally very different with respect to volcanoes of Mesozoic age, for though Lyell stated with doubt, that volcanic products of Jurassic date are found in the Morea and in the Apennines; and Medlicott and Blanford consider that probably the igneous rocks of Rajmahal may be of that age, we must, perhaps, wait for further information before the question may be considered as finally settled. Of Jurassic age no actual craters remain. Darwin also has stated, on good grounds, that in the Andes a line of volcanic eruptions has been at work from before the deposition of the Cretaceo-oolitic formation down to the present day.

In the British Islands we have a remarkable series of true volcanic rocks, the chronology of which has been definitely determined. The oldest of these belongs to the Lower Silurian epoch, as shown, for example, on a large scale in Pembrokeshire, at Builth in Radnorshire, in the Longmynd country west of the Stiper stones in Shropshire, and on a far greater scale in North Wales and Cumbria. Of later date we find volcanic lavas and ashes in the Devonian rocks of Devon, and in the Old Red Sandstone of Scotland. The third series is plentiful among the Carboniferous rocks of Scotland, and in a smaller way interstratified with the Coal-measures of South Staffordshire, Warwickshire and the Clee Hills. The fourth series chronologically is associated with the Permian strata in Scotland, and the fifth and last consists of the Miocene basaltic rocks of the Inner Hebrides and the mainland of the West of Scotland.

In the British Islands the art of geological surveying has, I believe, been carried out in a more detailed manner than in any other country in Europe, a matter which has been rendered comparatively easy by the excellence of the Ordnance Survey maps both on the 1-inch and the 6-inch scales. When the whole country has been mapped geologically little will remain to be done in geological surveying, excepting corrections here and there, especially in the earliest published maps of the South-west of England. Palæontological detail may, however, be carried on to any extent, and much remains to be done in microscopic petrology which now deservedly occupies the attention of many skilled observers.

Time will not permit me to do more than advert to the excellent and well-known geological surveys now in action in India, Canada, the United States, Australia, New Zealand, and South Africa.

On the Continent of Europe there are National Geological Surveys of great and well-deserved repute conducted by men of the highest eminence in geological science, and it is to be hoped the day may come when a more detailed survey will follow the admirable map executed by Sir Roderick Murchison, De Verneuil, and Count Keyserling, and published in their joint work, "The Geology of Russia in Europe and the Ural Mountains."

It is difficult to deal with the Future of Geology. Probably in many of the European formations more may be done in tracing the details of subformations. The same may be said of much of North America, and for a long series of years a great deal must remain almost untouched in Asia, Africa, South America, and in the islands of the Pacific Ocean. If, in the far future, the day should come when such work shall be undertaken, the process of doing so must necessarily be slow, partly for want of proper maps, and possibly in some regions partly for the want of trained geologists. Palæontologists must always have ample work in the discovery and description of new fossils, marine, freshwater, and truly terrestrial; and besides common stratigraphical geology, geologists have still an ample field before them in working out many of those physical problems which form the true basis of Physical Geography in every region of the earth. Of the history of the earth there is a long past, the early chapters of which seem to be lost for ever, and we know little of the future except that it appears that "the stir of this dim spot which men call earth," as far as Geology is concerned, shows "no sign of an end."

[1] I must also, with much pleasure, advert to Prof. Prestwich's inaugural lecture when installed in the Chair of Geology at Oxford in 1875, the subject of which is "The Past and Future of Geology."

SECTION D

BIOLOGY

Opening Address by Richard Owen, C.B., F.R.S., President of the Section

The recent construction of the edifice of the British Museum (Natural History), Cromwell Road,[1] and the transference thereto of three of the Departments, the systematic arrangement of which in their respective galleries approaches closely to completion, have left me little leisure in the present year for other scientific work. The expression, moreover, in divers forms and degrees of the satisfaction and instruction such partial exhibition of the national treasures of natural history has afforded to all classes of visitors since the galleries were open to the public, in April last, encourages me to believe that a few words on this great additional instrument in advancing biological science may not be unacceptable to the Section of the British Association which I have now the honour to address.

It is true that when we last met at Swansea, my accomplished colleague, Dr. Albert Günther, F.R.S., selected a general description of the building as the subject of his address to Section D.

I was unwilling then, in consideration of the time of the Section already given to the matter, to respond to appeals of some of our fellow-members for information as to how, and through whom, the new Museum came to be, and to be where it is; but now, honoured by my present position, I venture to hope that a brief outline of its genetic history, which I have been preparing for publication in a fuller form, may be condoned.

In the actual phase of our Science, its cultivators, especially the younger generation, do not rest upon the determination and description, however minute and exhaustive, of the acquisitions so rapidly accumulating of objects or "new species"; but devote themselves also, and more especially, to the investigation of their developmental phenomena.

It has, therefore, seemed to me that it would not be inappropriate, as being germane to the present phase of research, to submit to the Section a few words on the genesis of this new national edifice, generously provided by the State for the promotion of Biology.

On the demise, in 1856, of Sir Henry Ellis, K.T., then Principal Librarian of the British Museum, the Government, made aware of the growth of the Departments of natural history, more especially of geology and palæontology, since the foundation of the Museum in 1753, when the collections of printed books and manuscripts predominated, determined that, together with a principal librarian, there should be associated a new official having special charge of the collections of natural history, but under similar subordinate relations to the Trustees. To this official was assigned the title of "Superintendent of the Departments of Natural History," and I had the honour to be selected for this office.[2]

Almost my first work was to ascertain the extent of my charges, and I confess that I was unprepared to find that the galleries assigned for the arrangement and public exhibition of the several natural history series in the British Museum were so inadequate to these ends as to necessitate the storage of many unexhibited, and in great proportion rare and valuable specimens. This condition affected principally the collection of fossil remains, but in not much less degree that of the recent natural history.

One of my colleagues, Mr. Charles König, then Keeper of the Department of Mineralogy, and most eminent in that science, applied the gallery assigned thereto principally to the rare and beautiful specimens of his favourite subject. When the newer science of palæontology entered upon its rapid growth, and, on the demise of Mr. König, led to the formation of a distinct Department of Geology, the proportion of the British Museum set apart for natural history could not afford for the exhibition of the fossils and rock specimens more or other space than might be gained from or intercalated among the mineral cabinets in one and the same gallery, viz. that which had been originally assigned to Mr. König.

The store-vaults in the basement of the Museum became accordingly invaded by the rapidly-accumulating unexhibited geological specimens, as those receptacles had been, and continued to be, needed for the storage of such specimens, and especially the osteological ones, of the Department of Zoology.

[1] The official designation assigned by the Trustees to the building and its contents.

[2] The date of my appointment is May 26, 1856.

In 1854 Dr. John Ed. Gray, Keeper of the Zoology, reported on the unfitness of the locality of his stored specimens, and prayed for additional accommodation for them.[1] But, on the report of the architect, to whom such appeal was referred, the Trustees "declined to adopt Dr. Gray's suggestion," and recommended "that steps should be taken to obviate the deterioration of the specimens complained of by Dr. Gray in consequence of the damp condition of the vaults in which they are contained."[2] To renewed appeals by the experienced Keeper, and agreeably with his ideas on the nature and extent of the required additional space for the zoology, the Trustees recommended:—"An additional gallery to the Eastern Zoological Gallery, and the substitution of skylights for the side windows," with a view to an additional gallery at an elevation above the floor of the one in use; they also resolved:—"That accommodation be provided for the officers of the Natural History Departments on the roof of the Print-room."[3]

But the inadequacy for exhibition purposes of additional space which might be gained by the new gallery, or by the accessory wall-gallery attainable by stairs in the one in use,[4] was so impressed on my convictions, that I determined, in 1857, to submit to the Trustees a statement embodying estimates of space required for exhibition of all and several the departments of natural history, with the grounds of such estimates, including considerations based upon the ratio of increase during the ten years preceding my appointment, and the conditions likely to affect the proportional number of future annual additions.

This purpose, which I deemed a duty, I endeavoured to effect in a "Report, with a Plan," submitted on February 10, 1859, which Report, being forwarded by the Trustees to the Treasury, and being deemed worthy of consideration by Parliament, was "Ordered by the House of Commons to be printed, 11th March, 1859," and can still be obtained at the Office of Parliamentary Papers or Blue Books.[5]

The Report included, as I have stated, estimates of space for the then acquired specimens of the several departments of natural history, together with space for the reception of the additional specimens which might accrue in the course of a generation, or thirty years. It further recommended that such museum-building, besides giving the requisite accommodation to the several classes of natural history objects, as they had been by authority exhibited and arranged for public instruction and gratification, should also include a hall, or exhibition-space for a distinct department, adapted to convey an elementary knowledge of the subjects of all the divisions of natural history to the large proportion of public visitors not specially conversant with any of those subjects.

I may crave permission to quote from that part of my Report which has received the sanction of the "Commission on the Advancement of Science" of 1874: "One of the most popular and instructive features in a public collection of natural history would be an apartment devoted to the specimens selected to show type-characters of the principal groups of organised and crystallised forms. This would constitute an epitome of natural history, and should convey to the eye in the easiest way an elementary knowledge of the sciences."[6]

An estimate of the space required for such apartment is given, and it has been obtained in the new Museum of Natural History.

I ventured also on another topic in connection with the more immediate object of my Report. Previous experience at the museum of the Royal College of Surgeons had impressed me with the influence on improved applications of collections and on the ratio of their growth, through Lectures expository of their nature. I felt confident that, with concurrence of authorities, both relations would be exemplified under the actual superintendence at the British Museum. Moreover, such museum of natural history has wider influences over possessors and collectors of rarities and of desiderated specimens than one of restricted kind, as in Lincoln's Inn Fields. I concluded my Report, therefore, by referring to the lecture theatre shown in

[1] See Parliamentary Paper, or Blue Book, folio 1858, entitled:—"Copies of all Communications made by the Officers and Architect of the British Museum to the Trustees, respecting the want of space for exhibiting the Collections in that Institution," p. 4. [2] *Ib.* p. 5. [3] *Ib.* p. 25 and p. 28.

[4] In his report of December 29, 1856, Dr. Gray states:—"Scarcely half of the zoological collections is exhibited to the public, and their due display would require more than twice the space devoted to them."—*Ib.* p. 21. To any removal of the natural history to another site Dr. Gray was strongly opposed.

[5] Parliamentary Papers, "Report with Plan," &c. (126, i.), fol. 1859.

[6] Report, *ut suprà*, p. 22.

my plan, and expressed my belief that "Administrators will consider it due to the public that the gentlemen in charge of the several departments of the National Collection of Natural History should have assigned to them the duty of explaining the principles and economical relations of such departments, in elementary and free lectures, as, *e.g.* on Ethnology, Mammalogy, Ornithology, Herpetology and Ichthyology, Malacology and Conchology, Entomology, Zoophytology, Botany, Geology, Palæontology, Mineralogy."

After the lapse of twenty years I have lived to see the fulfilment of all the recommendations, save the final one, of my Report of 1859. The lecture-theatre was erased from my plan, and the elementary courses of lectures remain for future fulfilment.

Considering that, in the probable communication of this Report to Parliament, I was addressing the representatives of the greatest commercial and colonising nation in the globe, representatives of an empire exercising the widest range of navigation and supreme in naval power, such nation and empire might well be expected by the rest of the civilised world to offer to students and lovers of natural history the best and noblest museum of the illustrations of that great division of general science.

But for such a museum, a site or superficial space of not less than eight acres was asked for, the proportion of such space to be occupied by the proposed building being, at first, limited, and dependent upon its architectural arrangement in one, two, or more storeys. But the effect of restricting the site or available superficial space to that, *e.g.* on which the Museum at Bloomsbury now stands, was significantly demonstrative of difficulties to come, and concomitantly indicative of the administrative wisdom which would be manifested by securing, in a rapidly growing metropolis, adequate space for future additions to the building which might be in the first place erected thereupon.

Nevertheless one or two of my intimate and confidential friends dissuaded me from sending in a Report which might be construed or misinterpreted as exemplifying a character prone to inconsiderate and extravagant views, and such as might even lead to disagreeable personal consequences. Moreover the extent of space reported for seemed inevitably to involve change of locality. Two of my colleagues occupied the elegant and commodious residences attached to the British Museum; and it was possible that provision for such residences marked in the plan which accompanied my Report might not be adopted. Moreover no statement of grounds for adequate space requirements for the whole of the National Museum of Natural History had previously been submitted to authority. The legislative mind had not been prepared for calm and due consideration of the subject. Still I flattered myself that, by whomsoever the details and aims and grounds of my Report were known and comprehended, any strong opposition on the part of Parliament could hardly be expected. Nevertheless, an Irish Member seeing a way to a position in the House which is gained by the grant of a Committee of Inquiry, of which the Mover becomes Chairman, made my Report and Plan the ground of a motion to that effect, which was carried. The Select Committee, after taking the evidence published in the Blue Book (ordered to be printed August 10, 1860, quarto, pp. 238, with ten plans), reported against the removal of the Natural History Collections from the British Museum. As to the chief reasons alleged for such removal the Report states that with one "eminent exception the whole of the scientific naturalists examined before your Committee, including the Keepers of all the Departments of Natural History in the British Museum, are of opinion that an exhibition on so large a scale tends alike to the needless bewilderment and fatigue of the public, and the impediment of the studies of the scientific visitor . . . . Your Committee, therefore, recommend the adoption of the more limited kind of exhibition advocated by the other witnesses, in preference to the more extended method recommended by Prof. Owen."

Lest however the House might attach undue weight to the exceptional testimony, the chairman of the Committee deemed it his duty, in bringing up the Report, to warn the House of the character of such testimony, and his speech left, as I was told, a very unfavourable impression as regards myself. I was chiefly concerned to know what might be put upon record in "Hansard." In that valuable work hon. members revise their reported utterances before the sheets go to press. I was somewhat relieved to find Mr. Gregory regretting that "a man whose name stood so high should connect himself with so foolish, crazy, and extravagant a scheme, and should persevere in it after the folly had been pointed out by most unexceptionable witnesses. . . . "They had on one side, and standing alone, Prof. Owen and his ten-acre scheme, and on the other side all the other scientific gentlemen, who were perfectly unanimous in condemning the plan of Prof. Owen as being utterly useless and bewildering. . . . "Among these gentlemen were Prof. Huxley, Prof. Maskelyne, Mr. Waterhouse, Dr. Gray, Sir Roderick Murchison, Mr. Thomas Bell, P.G.S., Dr. Sclater, Sec.Z.S., Mr. Gould, and Sir Benjamin Brodie. To give the House some idea of that gigantic plan, he might mention that a part of it consisted of galleries 850 feet in length for the exhibition of whales. The scientific men examined on the subject, one and all, disapproved of that plan *in toto;* and they advocated what was technically called a 'typical mode of exhibition.'"[1]

In point of fact that Supplementary Exhibition Room which was planned and recommended for the purpose I have already cited, was urged by the instructor of Mr. Gregory as the sole reasonably required National Museum of Natural History, for which the nation ought to be called upon to provide space and funds, a conclusion subsequently adopted and unanimously recommended by the Royal Commission on Science.[2]

Although grief was natural and considerable at this result, not without mortification at the reception by Parliament of the "Report and Plan" submitted thereto, I now feel grateful that the sole responsibility of their author is attested in the pages of a Work[3] which will last as long as, and may possibly outlast, the great legislative organisation whose debates and determinations are therein authoritatively recorded.

I was not, however, cast down, nor did I lose either heart or hope; I was confident in the validity of the grounds of my appeal, and foresaw in the inevitable accumulations year by year, the evidence which would attest its soundness and make plain the emergency of the proposed remedy.

Moreover, there was one who, though not a naturalist, had devoted more time, pains, and thought to the subject than had been bestowed by any—whether naturalist or administrator—who testified adversely thereon. The Right Hon. William Ewart Gladstone, an elected Trustee of the British Museum, took nothing on trust; he explored with me in 1861 every vault and dark recess in the Museum which had been or could be allotted to the non-exhibited specimens of the natural history, those, viz. which it was my aim to utilise and bring to light. He gave the same attention to the series selected for exhibition in the public galleries, and appreciated the inadequacy of the arrangements to that end. He listened to my statements of facts, to the grounds of prevision of annual ratios of increase, to the reasons for providing space therefor, to my views of the aims of such exhibitions, and to the proposed extended applications and elucidations of the collections. Mr. Gladstone tested every averment, and elicited the grounds of every suggestion, with a tact and insight that contrasted strongly with the questionings in Mr. Gregory's committee-room, where too often vague interrogations met with answers to match.

Conformably with Mr. Gladstone's convictions, he as Chancellor of the Exchequer moved, May 12, 1862, for "Leave to bring in a Bill for removal of portions of the Trustees' Collections in the British Museum."

On May 19, when the Bill was to be read a second time, a new, unexpected, and formidable antagonist arose. Mr. Disraeli early got the attention of the House to a speech, warning hon. members of the "progressive increase of expenditure on civil estimates," and laying stress on the fact that the "estimates of the actual year showed no surplus."[4] The influence of this advocacy of economy is exemplified in the debate which ensued. For repetitions of the nature and terms of objections to the Report and plan, as already denounced by Mr. Gregory, Mr. Bernal Osborne, and others, reference may be made to the volume of "Hansard" cited below. An estimable hon. member, whose words had always and deservedly carried weight with the country party, lent his influence to the same result. Mr. Henley, representative of Oxfordshire, said:—"All the House knew was that a building was to be put up somewhere. He considered this a bad way of doing business, particularly at a time when nobody could be sanguine that the finances of the country were in a flourishing state. Let the stone once be set rolling, and then all gentlemen of science and taste would have a kick at it, and it would be knocked from one

[1] "Hansard." Debate of July 22, 1861, pp. 1861, 1918.
[2] Fourth Report, p. 4. [3] "Hansard," *ut supra.* [4] *Ib.* 1862, p. 1927.

to the other, and none of them probably would ever live to see an end of the expense."[1]

Permit me to give one more example of the baneful influence of the opening speech on our great instrument of scientific progress. Mr. Henry Seymour, Member for Poole, said:—"If a foreigner had been listening to the debates of that evening it must have struck him that it was, to say the least, a rather curious coincidence that a proposal to vote 600,000*l.* for a new collection of birds, beasts, and fishes at South Kensington should have been brought forward on the very evening when the Leader of the Opposition had made a speech denouncing that exorbitant expenditure—a speech, he might add, which was re-echoed by many Liberal members of the House."[2]

It was however not a "curious," but a "designed coincidence." Mr. Disraeli, knowing the temper of the House on the subject, and that the estimates for the required Museum of Natural History were to be submitted by Mr. Gladstone, chose the opportunity to initiate the business by an advocacy of economy which left its intended effect upon the House. In vain Lord Palmerston, in reply to the Irish denunciators, proposed as a compromise to "exclude whales altogether from disporting themselves in Kensington Gardens."[3] The Government was defeated by a majority of ninety-two, and the erection of a National or British Museum of Natural History was postponed, to all appearance indefinitely, and in reality for ten years.

Nevertheless, neither averments nor arguments in the House on May 19, 1862, nor testimonies in the hostile Committee of 1860, 1861, had shaken my faith in the grounds on which the "Report and Plan of 1859" had been based. The facts bearing thereupon, which it was my duty to submit in my "Annual Reports on the Natural History Departments of the British Museum," would, I still hoped, have some influence with hon. members of the legislature, to whom those Reports are transmitted.

The annual additions of specimens continued to increase in number and in value year by year. I embraced every opportunity to excite the interest of lovers of natural history travelling abroad and of intelligent settlers in our several colonies to this end, among the results of which I may cite the reception of the Aye-Aye, the Gorilla, the Dodo, the Notornis, the maximised and elephant-footed species of Dinornis, the representatives of the various orders and genera of extinct Reptilia from the Cape of Good Hope, and the equally rich and numerous evidences of the extinct Marsupialia from Australia, besides such smaller rarities as the animals of the Nautilus and Spirula.

Wherever room could be found in the exhibition galleries at Bloomsbury for these specimens, stuffed or as articulated skeletons, or as detached fossils, they were squeezed in, so to speak, to mutely manifest to all visitors, more especially administrative ones, the state of cram to which we were driven at Bloomsbury.

Another element of my Annual Reports was the deteriorating influence on valuable specimens of the storage vaults and the danger of such accumulations to the entire Museum and its priceless contents. And here perhaps you may deem some explanation needful of the grounds of the latter consideration addressed to economical granters of the national funds.

The number of specimens preserved in spirits of wine amounted to thousands; any accidental breakage, with conflagration, in the subterraneous localities contiguous with the heating-apparatus of the entire British Museum, would have been as destructive to the building as the gunpowder was meant to be when stored in the vaults beneath King James's Houses of Parliament.

At this crisis the "Leading Journal," after the stormy debate of May 19, 1862, made the following appeal to me:—"Let Mr. Owen describe exactly the kind of building that will answer his purpose, that will give space for his whales and light for his humming-birds and butterflies. The House of Commons will hardly, for very shame, give a well-digested scheme so rude a reception as it did on Monday night."[4]

My answer to this appeal was little more than some amplification, with additional examples, of the several topics embodied in the original Report. The pamphlet "On the Extent and Aims of a National Museum of Natural History," with reduced copies of the plans, went through two editions, and no doubt had the effect anticipated by the able Editor.

Another element of reviving hope was the acceptance by Mr. Gregory of the government of a tropical island.

The sagacious Prime Minister accurately gauged the modified feeling—the subsiding animosity—of Parliament on the subject, and submitted (June 15, 1863) a motion "for leave to purchase five acres for the required Natural History building." The choice of locality he left to honourable members. Lord Palmerston pointed out that the requisite extent of site could be obtained at Bloomsbury for 50,000*l.* per acre, and that it could be got at South Kensington for 10,000*l.* per acre; and his lordship distinctly stated that the space, in either locality, would be bought for the purpose of a Museum of Natural History. The purchase of the land at South Kensington was accordingly voted by 267 against 135, and thus the Government proposition was carried by a majority of 132. By this vote the decision of Mr. Gregory's Committee was virtually annulled.

In a conversation with which I was favoured by Lord Palmerston, I interposed a warning against restriction of space, and eventually eight acres of ground were obtained, including the site of the Exhibition Building of 1862, opposite Cromwell Gardens, and that extent of space is now secured for actual and prospective requirements of our National Museum of Natural History.

I am loth to trespass further on the time of the Section, but a few words may be expected from me of the leading steps to the acquisition of the present edifice, occupying a portion—about one-third—of that extent of ground.

Mr. Gladstone, adhering to the convictions which led him to submit his financial proposition of May, 1862, honoured me, at the close of that session of Parliament, with an invitation to Hawarden to discuss my plans for the Museum Building; and, after consideration of every detail, he requested that they might be left with him. He placed them, with my written expositions of details, in the hands of Sir Henry A. Hunt, C.B., responsible adviser on buildings, &c., at the Office of Works, with instructions that they should be put into working form, so as to support reliable estimates of cost. I was favoured with interviews with Sir Henry, resulting in the completion of such working plans of a museum, including a central hall, an architectural front of two storeys, and the series of single-storeyed galleries extending at right angles to the front, as shown in my original Plan. I was assured that such plan of building affording the space I had reported on, would be the basis to be submitted to the professional Architect whenever the time might arrive for Parliamentary sanction to the cost of such building.

Here I may remark that experiments which preceded the substitution, in 1835, of the actual Museum of the Hunterian Physiology at the Royal College of Surgeons, for the costly, cumbrous, and ill-lit building, with its three-domed skylights, which preceded it, had led to the conclusion that the light best fitted for a museum was that in which most would be reflected from the objects and least directly strike upon the eye; and this was found to be effected by admittance of the light at the angle between the wall and roof. But this plan of illumination is possible only in galleries of one storey, or the topmost in a many-storeyed edifice. Such system of illumination may be seen in every gallery of the museum described to you last year at Swansea, save those of the storeys of the main body below the sky-lit one which necessitate side windows.

I subjoin a copy of the letter from Sir Henry A. Hunt, conveying his conclusions respecting the plan of building discussed with him:—

"4, *Parliament Street, September* 25, 1862

"My Dear Sir,—I return you the drawings of the proposed Museum of Natural History at South Kensington. In May last I told Mr. Gladstone that the probable cost of covering five acres with suitable buildings would be about 500,000*l.*, or 100,000*l.* per acre.

"The plan proposed by you will occupy about four acres, and will cost about 350,000*l.*, or nearly 90,000*l.* per acre.

"Having prepared sketches showing the scheme suggested by you, I have been able to arrive more nearly at the probable cost than I had the means of doing in May last. But, after all, the difference is not great; although the present estimate is a more reliable one than the other. It is right, however, to state that the disposition of the building as proposed by you will give a greater amount of accommodation, and admit of a cheaper mode of construction, than I had calculated upon in May (relatively with the space intended to be covered), and therefore I think your plan far better adapted for the Museum than the plan I took the liberty to suggest to Mr. Gladstone.

"Believe me, &c,

"(Signed) Henry A. Hunt"

[1] "Hansard," p. 1932. [2] *Ib.* 1862, p. 1918. [3] *Ib.* p. 1931.
[4] The *Times*, May 21, in a leader on the Museum Debate.

Sir H. A. Hunt had previously formed an estimate of cost for the Chancellor of the Exchequer on inspection of the Report and plan in the Parliamentary paper of March, 1859. The letter to which I refer I regard as an antidote to some previous quotations from adverse members of Parliament.

The working plans of Sir Henry A. Hunt were subsequently submitted for competition, and the designs of the accomplished and lamented Capt. Fowke, R.E., obtained the award in 1864. His untimely death arrested further progress or practical application of the prize designs.

In 1867 Lord Elcho pressed upon the House of Commons, through the Hungerford Bridge Committee, the Thames Embankment as a site for the New Museum of Natural History, but unsuccessfully. The debates thereon, nevertheless, caused some further delay.

In 1871 a vote of 40,000*l.* for beginning the Museum Buildings at South Kensington was carried without discussion. In 1872 a vote of 29,000*l.* for the same building was opposed by Lord Elcho, but was carried by a majority of 40 (85 against 45).

On the demise of Capt. Fowke Mr. Alfred Waterhouse was selected as architect. He accepted the general plans which had been sanctioned and approved by Sir H. A. Hunt and by Capt. Fowke, and I took the liberty to suggest, as I had previously done to Capt. Fowke, that many objects of natural history might afford subjects for architectural ornament; and at Mr. Waterhouse's request I transmitted numerous figures of such as seemed suitable for that purpose. I shall presently refer to the beautiful and appropriate style of architecture which Mr. Waterhouse selected for this building, but am tempted to premise a brief sketch of what I may call the "Genealogy of the British Museum," or what some of my fellow-labourers, agreeably with the actual phase of our science, may prefer to call its "Phylogeny."

Sir Hans Sloane, M.D., after a lucrative practice of his profession in the then flourishing colony of Jamaica, finally settled at Chelsea, and there accumulated a notable museum of natural history, antiquities, medals, cameos, &c., besides a library of 50,000 volumes, including about 350 portfolios of drawings, 3500 manuscripts, and a multitude of prints. These specimens were specified in a MS. catalogue of thirty-eight volumes in folio, and eight volumes in quarto. Sir Hans valued this collection at the sum of 80,000*l.*; but at his death, in 1753, it was found that he had directed in his "Will" that the whole should be offered to Parliament for the use of the public on payment of a minor sum, in compensation to his heirs. This offer being submitted to the House of Commons, it was agreed to pay 20,000*l.* for the whole. At the same time the purchase of the Cottonian Library and of the Harleian MSS. was included in the Bill.[1]

The following are the terms of the enactment:—

Act 26, George II., Cap. 22 (1753).—*Sections IX. and X.*

"(IX.) And it be enacted by the authority aforesaid, that within the cities of London or Westminster or the suburbs thereof, one general repository shall be erected or provided in such convenient place and in such manner as the trustees hereby appointed, or the major part of them, at a general meeting assembled, shall direct for the reception not only of the said museum or collection of Sir Hans Sloane, but also of the Cottonian Library and of the additions which have been or shall be made thereunto by virtue of the last will and testament of the said Arthur Edwards, and likewise of the said Harleian collection of manuscripts and of such other additions to the Cottonian Library as, with the approbation of the trustees by this Act appointed, or the major part of them, at a general meeting assembled, shall be made thereunto in manner hereinafter mentioned, and of such other collections and libraries as, with the like approbation, shall be admitted into the said general repository, which several collections, additions, and library so received into the said general repository shall remain and be preserved therein for public use to all posterity.

"(X.) Provided always that the said museum or collection of Sir Hans Sloane, in all its branches, shall be kept and preserved together in the said general repository whole and entire, and with proper marks of distinction."

[1] In his letter of February 14, 1753, to his friend Mann, Horace Walpole, then Member for Lynn, writes:—"You will scarce guess how I employ my time, chiefly at present in the guardianship of embryos and cockle-shells. Sir Hans Sloane is dead, and has made me one of the trustees of his museum, which is to be offered for twenty-thousand pounds to the King and Parliament and (in default of acceptance) to the Royal Academies of Petersburg, Berlin, Paris, and Madrid. He valued it at four-score thousand, and so would any one who loves hippopotamuses, sharks with one ear, and spiders as big as geese. The king has excused himself, saying he did not think that there were twenty thousand pounds in the Treasury."—"Letter to Horace Mann," 8vo, vol. iv. p. 32.

The trustees appointed under the Act are of four classes: Royal, Official, Family, and Elected. The first class includes one trustee appointed by the Sovereign; the second class includes the Lord Archbishop of Canterbury, the Lord High Chancellor, the Speaker of the House of Commons, and twenty-two other high officials and presidents of societies. The three first in this class are designated "Principal Trustees," and in them is vested the patronage or appointment to every salaried office save one in the British Museum; the exception being the Principal Librarian, who is appointed by the Sovereign. Of the Family Trustees, the Sloane collections are now represented by the Earl of Derby and the Earl of Cadogan, the Cottonian Library by the Rev. Francis Annesley and the Rev. Francis Hanbury Annesley, the Harleian manuscripts by Lord Henry, C. G. Gordon-Lennox, M.P., and by the Right Hon. George A. F. Cavendish Bentinck, M.P. Among the Elected Trustees the honoured name of Walpole, associated with the origin of the British Museum, is continued by the Right Hon. Spencer Horatio Walpole, M.P., to whom the requisite Parliamentary business of the Museum is usually confided.

I may call attention to "the suburbs of London or Westminster" as one of the localities specified in the original Act of Parliament, and such situation was selected for the locality of the Library and the Museum. The Government issued lottery-tickets to the amount of 300,000*l.*, out of the profits of which the 20,000*l.* for the Sloanian Museum was paid and purchase made of a suitable building, with contiguous grounds for its reception and the lodgment of keepers.

To the north of the metropolis, about midway between the two cities of London and Westminster, there stood, in 1753, an ancient family mansion called Montague House. This is defined by Smollet in his "History of England" as "one of the most magnificent edifices in England."[1] Its style of architecture was that of the Tuilleries in Paris. From London it was shut off by a lofty brick wall, in the middle of which was a large ornamental gateway and lodge, through which, in my earlier years as a student of natural history, I have often passed to inspect, through the kindness of the then keepers of mineralogy and zoology, and make notes on, the Sloanian and subsequently-added rarities.

To the north of Montague House were the extensive gardens, beyond which stretched away a sylvan scene to the slopes of Highgate and Hampstead Hills.

The original location of the British Museum was more apart and remote from the actual metropolis and less easy of access than is the present Museum of Natural History at the West End.

The additions to the natural history series, which accrued from 1753 to 1833, together with the growth of other departments, necessitated provision of corresponding conservative and exhibition spaces. These were acquired by the erection, on the site of Montague House, of the present British Museum, the architect, Sir Sidney Smirke, adopting the Ionic Greek style.

The extent of space afforded by this edifice in comparison with that of its predecessor was such as to engender a conviction that it would suffice for all subsequent additions. The difficulty in our finite nature and limited capacity of looking forward is exemplified in such names as New College at Oxford, Newcastle, New Street, New Bridge, &c., as if nothing was ever to grow old; and the same restricted power of outlook affects our provision of requirements of space for ever-growing collections.

The Printed Book Department, which took the lion's share of the then new British Museum, found itself compelled in the course of one generation to appropriate the quadrangle left by Smirke in order to admit light to the windows of the galleries, looking that way or inwards.

From analogy I foresee that some successor of mine may exemplify human short-sightedness in my limit of demand to eight acres for the growth of the present Museum.

However, these acres, after conflicts stretching over a score or more of years, have at last been acquired for due display and facilities of study of the subjects of Section D.

Amongst the works of architectural art which adorn the metropolis, Westminster Abbey and St. Paul's Cathedral stand supreme. Of later additions may with them be named the noble example of the Perpendicular Gothic selected by Barry for the Houses of Parliament, and, I may be permitted to add, the new Law Courts, which exemplify the more severe style of the Thirteenth-century Gothic.

[1] Ed. 1825, p. 332.

Mr. Alfred Waterhouse, R.A., for the realisation of the plans and requirements of our Museum of Natural History, has chosen an adaptation of the Round-arched Gothic, Romanesque, or Romaic of the twelfth century. No style could better lend itself to the introduction, for legitimate ornamentation, of the endless beautiful varieties of form and surface sculpture exemplified in the animal and vegetable kingdoms. But the skill in which these varieties have been selected and combined to produce unity of rich effects will ever proclaim Mr. Waterhouse's supreme mastery of his art.

I need only ask the visitor to pause at the grand entrance, before he passes into the impressive and rather gloomy vestibule which leads to the great hall, and prepares him for the flood of light displaying the richly-ornamented columns, arcades, and galleries of the Index Museum.

In the construction of a building for the reception and preservation of perishable objects, the material should be of a nature that will least lend itself to the absorption and retention of moisture. This material is that artificial stone called terra-cotta. The compactness of texture which fulfils the purpose in relation to dryness is also especially favourable for a public edifice in a metropolitan locality. The microscopic receptacles of soot-particles on the polished surface of the terra-cotta slabs are reduced to a minimum; the influence of every shower in displacing those particles is maximised. I am sanguine in the expectation that the test of exposure to the London atmosphere during a period equal to that which has elapsed since the completion of Barry's richly ornamented palace at Westminster, now so sadly blackened by soot, will speak loudly in favour of Mr. Waterhouse's adoption of the material for the construction of the National Museum of Natural History. A collateral advantage is the facility to which the moulded blocks of terra-cotta lend themselves to the kind of ornamentation to which I have already referred.

In concluding the above sketch of the development of our actual Museum of Natural History, I may finally refer, in the terms of our modern phylogenists, to the traceable evidences of "ancestral structures." In the architectural details of the new Natural History Museum you will find but one character of the primitive and now extinct museum retained, viz. the Central Hall. In Montague House there were no galleries, but side-lit saloons or rooms of varying dimensions and on different storeys.

In its successor, the Museum developed on its site at a later period, we find galleries added: that, for example, which was appropriated to the birds and shells being 300 feet in length. This architectural organisation still exists at Bloomsbury.

The Museum, which may be said to have budded off, has risen to a still higher grade of structure after settling down at South Kensington. In its anatomy we find, it is true, the central hall and long side-lit galleries; but in addition to these inherited structures we discern a series of one-storeyed galleries, manifesting a developmental advance in the better admission of light and a consequent adaptation of the walls as well as the floor to the needs of exhibition.[1]

Should the Section, as did the Académie des Sciences in relation to the passage cited, kindly condone such application to human contrivances of the current genealogical or phylogenetic language applied to vital structures, your President need hardly own his appreciation of the vast superiority of every step in advance which is manifested in existing as compared with extinct organisms. And thus, sensible as far as human faculty may comprehend them, that organic adaptations transcend the best of those conceived by the ingenuity of man to fulfil his special needs, he would ask whether analogy does not legitimately lead to the inference, for organic phenomena, of an Adapting Cause operating in a corresponding transcendent degree?

In conclusion, I am moved to remark that a Museum giving space and light for adequate display of the national treasures of Natural History may be expected to exert such influence on the progress of Biology as to condone, if not call for, a narrative of the circumstances attending its formation in the Records of the British Association for the Advancement of Science.

[1] In the notable reply (*Annales des Sciences Naturelles*, 1829) to an illustration of the unity of composition or of plan in Cephalopods and Vertebrates, by bending one of the latter so as to bring the pelvis in contact with the nape, advocated by Geoffroy St. Hilaire, Cuvier did not deem it too trivial to call in architecture to elucidate his objections. "La *composition d'une maison*, c'est le nombre d'appartemens ou de chambres qui s'y trouve: et son *plan*, c'est la disposition réciproque de ces appartemens et de ces chambres. Si deux maisons contenaient chacune un vestibule, une antichambre, une chambre à coucher, un salon, et une salle à manger, on dirait que leur *composition est la même*; et si cette chambre, ce salon, &c., étaient au même étage arrangés dans le même manière, on dirait aussi que leur *plan est le même*. Mais si leur ordre était différent, si de plain-pied dans une des maisons, ces pièces étaient placées dans l'autre aux étages successifs, on dirait qu'avec une composition semblable ces maisons sont construites sur des plans différens" (p. 245).

OUR ASTRONOMICAL COLUMN

ENCKE'S COMET.—We continue the ephemeris of this comet in the contracted form adopted in NATURE, vol. xxiv. p. 292, from the calculations of Dr. O. Backlund of Pulkowa:—

At Berlin midnight

	R.A.	Decl.	Log. distance from Sun.	Log. distance from Earth.
	h. m. s.	° ′		
Sept. 2	4 23 4	+35 53·2	0·1659	0·0222
4	4 31 17	36 35·9		
6	4 40 7	37 19·2	0·1493	9·9885
8	4 49 38	38 3·0		
10	4 59 56	38 46·8	0·1317	9·9535
12	5 11 6	39 30·3		
14	5 23 16	40 12·8	0·1128	9·9173

30	7 48 5	42 24·9	0·0219	9·7776
Oct. 2	8 12 13	+41 40·4		

In 1848, when the perihelion passage occurred eleven days later than it will do in the present year, the comet was remarked to be "just visible" to the naked eye at Harvard Observatory, U.S., on the morning of October 9, when the theoretical intensity of light was 4·3, and it was "plainly visible" to the naked eye on the morning of November 4, with an intensity of 9·5. The latter is a greater value than will be attained at this appearance, the maximum being 7·5 on November 9. On October 10 the calculated brightness will be equal to that, when it was just visible without the telescope in 1848, but moonlight will interfere at the time. For about four weeks after September 10 the comet will not set in London. As we have already stated it will be nearest to the earth on October 11, and in perihelion on November 15.

[Since the above was in type we learn from Mr. A. A. Common that he detected Encke's comet with his three-feet reflector at Ealing, shortly before midnight on Saturday last. On the following night, when it was better seen, its diameter was about 2′, and there was a central condensation of light.]

SCHAEBERLE'S COMET.—This comet will soon be well observable in the other hemisphere. The following track depends upon elements which Dr. v. Hepperger has calculated from observations to August 11:—

At Berlin Midnight.

	R.A.	Decl.	Log. distance from Earth.	Intensity of light.
	h. m.	° ′		
Sept. 1	13 30·0	+11 27	9·8329	12·5
5	13 52·7	+ 1 41	9·8965	8·5
9	14 7·7	− 5 32	9·9606	5·7
13	14 18·1	10 52	0·0108	3·8
17	14 25·7	14 56	0·0725	2·6
21	14 31·4	18 8	0·1101	1·9
25	14 36·1	20 42	0·1601	1·4
29	14 40·0	22 51	0·1962	1·0
Oct. 3	14 43·5	24 41	0·2284	0·8
7	14 46·6	−26 16	0·2569	0·6

The intensity of light on July 18, the date of the first European observation, is taken as unity.

NOTES

THE Royal Gardens, Kew, have just received, through the kind exertions on their behalf of Sir Ferdinand von Mueller, K.C.M.G., F.R.S., Government Botanist, Melbourne, perhaps the most remarkable Australian Cycadaceous stem which has ever been imported into this country. It is about four feet high, five and a half feet in circumference, and weighs about six hundredweight. It is the type of a new species described by von

Mueller as *Macrozamia Moorei*, in honour of Mr. Charles Moore, F.L.S., the Director of the Botanic Garden, Sydney. The exhibition of two stems (of which that secured for and sent to Kew is one) in the Queensland Court at the Melbourne Exhibition, seems to have drawn attention to the species. The plants appear to have been obtained from the mountainous district near Springsure in Queensland, where specimens have been seen twenty feet in height, with a girth of six feet four inches, cones measuring two to three feet in length, and leaves seven feet long. The stem at Kew has been placed in the Palm House, where it can scarcely fail to be an object of interest. It is in excellent condition, and there is every reason to hope that it will in time push a new crown of leaves. But even if it does not it will at any rate form, as Sir Ferdinand von Mueller has suggested, a unique museum specimen.

THE *Gazette* contains the official notice of the appointment of a Royal Commission, consisting of Mr. Bernhard Samuelson, M.P., F.R.S., Prof. H. E. Roscoe, D.C.L., F.R.S., Mr. Philip Magnus, Mr. John Slagg, M.P., Mr. Swire Smith, and Mr. William Woodall, M.P., "to inquire into the instruction of the industrial classes of certain foreign countries in technical and other subjects, for the purpose of comparison with that of the corresponding classes in this country; and into the influence of such instruction on manufacturing and other industries at home and abroad."

THE Queen has signified her pleasure to confer upon Mr. MacCormac, of St. Thomas's Hospital, Honorary Secretary-General of the late International Medical Congress, the honour of knighthood.

THE Meteorological Station to be erected at Pavia will be under the direction of Prof. Cantoni, who will establish a station for terrestrial physics, for the investigation of the influence of heat, light, electricity, &c., on vegetation in general, and some cultivations in particular, and also for the observation of the diurnal and annual variations of terrestrial magnetism.

THE scientific activity of Paris is at present almost exclusively concentrated on electricity, and the Paris Electrical Exhibition will have a scientific significance which is quite unusual. The initiative has been taken by the German Government, which has sent several professors to deliver lectures on the objects exhibited by that nation. Dr. Christian, of the Physiological Museum of Berlin University, gives explanations every day at two o'clock of the galvanometers on the Siemens system constructed by him. On Monday M. du Moncel, Member of the Institute, delivered a lecture on Telegraphy at ten o'clock in the morning, and conducted his audience through the galleries to visit the instruments described by him. Other lectures have been advertised for the different days of the week from August 29 to September 3. The Exhibition was opened to the Press last Friday and to the public last Saturday, at night from eight to eleven.

THE electric tramway in Paris has at length begun to work, and has several times gone backwards and forwards. A single overhead tube was tried at first to convey the current, but it was found impossible to insulate the rail by which it returned. Two overhead copper tubes are now used, along each of which at the bottom runs a longitudinal slit. A wire passing through the slit is attached to the tramcar beneath, and above to a small wheel which runs freely in the copper tube. As the car advances it draws along the little wheels through each tube, and thus maintains the connection.

A NUMBER of natives of Tierra del Fuego are at present at the Jardin d'Acclimatation in Paris.

THE French Government have resolved to grant a subvention for erecting a statue in Franche Comté to Claude de Jouffroy as the inventor of steam vessels. The French Académie des Sciences at its last sitting adopted a report of M. de Lesseps in favour of Jouffroy's claim to that distinction and to public gratitude.

THE new botanical lecture theatre of the University of Edinburgh was used by Prof. Dickson for the first time during the past summer session. It is built from the plans of Mr. Robertson, of H.M. Board of Works, and is a large octagonal building lighted from the roof and by windows on six sides. It is seated for 600, and had this year to contain 450 students. The acoustic arrangements are perfect. The old lecture-room has been converted into a general laboratory, while the former laboratory becomes a private room. The practical teaching has been conducted as formerly by Mr. Geddes, lecturer on Zoology in the School of Medicine, assisted by Mr. J. M. Macfarlane, B.Sc. Besides the usual elementary class, a class for advanced workers has also been started, a considerable number of investigations have been prosecuted, and instruction in drawing has been provided. The latter arrangement has been peculiarly successful.

THE twelfth meeting of German Anthropologists was opened at Ratisbon on August 8 by the president, Prof. Fraas. Some 250 members were present. The secretary, Prof. Ranke, read the report on the widely-extended activity of the Society. Prof. Ohlenschläger (Munich) spoke on the Roman epoch in Bavaria and the excavations in the Roman burial-ground near Ratisbon. Other addresses were delivered by Professors von Virchow, Tischler, Undset, Groos, Mehlis, Klopfleich, Schaaffhausen, Vater and Török. The next meeting-place will be Frankfort.

THE second meeting of Austrian Anthropologists took place at Salzburg on August 12-16. Some 270 gentlemen were present, principally Germans, Norwegians, and Russians. Of eminent scientific men we may mention Prof. von Virchow, the travellers Dr. Holub and Dr. Nachtigal, Prof. Steub (Munich), and Prof. Johannes Ranke. Count Wurmbrand was elected president, and Baron von der Sacken vice-president. Addresses were delivered by Herren Prinzinger, Much, and Zillner on the ancient inhabitants of Noricum, which the former two said were Germans; Herr Zillner however believed them to have been Kelts. On the second day Crown-Prince Rudolf took part in the meeting. Count Wurmbrand spoke on the development of the forms of bronzes and clay vessels, Herr Wolderich on prehistoric dogs, Holub on the South African negro tribes. Herr Maska reported on the discoveries near Schamberg, and Professors von Virchow and Schaaffhausen had an animated debate on the jaw of Neutitschein. Other addresses were delivered by Professors Tischler, Luschan, von der Sacken, Müllner, and Schaaffhausen. The usual excursions terminated the meeting.

THE death is announced of Prof. L. Spangenberg, director of the technical Versuchsanstalt and Professor of the Engineering Sciences at the Technical High School of Berlin. He died on August 6 last.

THE celebrated Egyptologist, Brugsch Pacha, has changed his residence from Cairo to Berlin, where he will lecture at the University.

THE European Vice-Consul at Tchesme telegraphs to Constantinople on August 27 that Tchesme and Chio were, on the night of the 26th, visited by an earthquake still more terrible than that of the 3rd of April. The destruction of property, he says, is considerable, and the inhabitants are in despair. Contemporaneously with the shocks of earthquake felt at Chio and Tchesme, the earth at Zante is reported to have suddenly given

out intense heat, accompanied by a strong breeze from the east, causing much alarm. These phenomena, however, subsided immediately. On the 24th inst. the entire island was enveloped in smoke, clouds from the west-south-west obscuring the sea from noon until dusk. Masses of calcined leaves also fell throughout the island.

A SEVERE shock of earthquake is reported to have been experienced in the mining district of Teversal, in Nottinghamshire, about noon on Friday last. In one of the pits belonging to the Stanton Ironworks Company the miners were so alarmed at the shock and the accompanying noise, that, thinking an explosion had occurred, they rushed to the mouth of the pit. In the Pear Tree Inn, Fackley, bricks were removed from the chimney, and the same thing was noticed in a house at Teversal. The station-master at the latter village, while sitting in his house, was thrown from his seat by the shock, and a quantity of plaster was detached from the ceiling. There was no explosion in the mines or other circumstance to account for the phenomena, and an upheaval of the floor of one of the pits indicated that the cause of disturbance was below the workings. One of the pits is 430 yards deep. The shock travelled in a north-west direction.

THE programme of the Congress of German Antiquarians, which will meet at Frankfort on September 11-15, has now been published. On the 11th the twenty-five years jubilee of the Frankfort Antiquarian Society will be celebrated.

THE professorship of Natural History and Geology at the Royal Agricultural College, Cirencester, vacant by the resignation of Prof. M. G. Stuart, has been filled by the appointment of Mr. Allen Harker, late of the Zoological Station, Naples.

ONE of the exhibits at the International Medical and Sanitary Exhibition was a "Compact School Collection for Use in Teaching the Chemistry of Foods," suggested by W. Stephen Mitchell, M.A. This form of case has been arranged for the purpose of affording, at a low cost, help to teachers in giving demonstrations on the chemistry of foods. The leading idea is that the teachers will be able to have on the walls of their schoolrooms the actual objects they are talking about, and the children will be familiarised by having always before them, not simply words or diagrams, but samples of the things themselves. Mr. Mitchell believes, as he stated in a paper read before the Society of Arts and the Domestic Economy Congress held at Birmingham, that with such diagrams as he showed, having lines of different lengths to represent quantities, greater accuracy of the knowledge of quantities can be conveyed than by showing the measured quantities in heaps as is the plan adopted at Bethnal Green. This does not get over the difficulty of showing the gases. Teachers must learn how to prepare these to show to their classes. The apparatus and materials for doing this are not costly, and are described in the "Shilling Chemistry Primer" published by Macmillan and Co. The cases are arranged with a sliding panel in front, so that the bottles can be taken out.

AT Castrop (Westphalia) a meteor was observed in the north-east sky on July 30 at 8.15 p.m. It moved in the direction from north-west to south-south-east. A meteoric stone weighing about 5 lbs. fell in the immediate vicinity of a field labourer, and penetrated into the ground to the depth of 1 metre. It was intensely hot, and was afterwards forwarded to Herr Oberbergrath Runge at Dortmund, in whose possession it now is.

ON August 15 the well-known Professor of Physics, Dr. Wilhelm Weber of Göttingen University, celebrated the day when, fifty years ago, he was called to that University from Halle. He is now seventy-seven years of age, and lectured until a few years ago.

A TERRIBLE catastrophe happened on August 16 at Remscheid (Rhenish Prussia). Suddenly the so-called Brennende Berg opened to the extent of some sixty to one hundred square metres and threw up gigantic flames. A house standing near sank into the burning gulf, and its inmates unfortunately perished. It is believed that the disaster was caused by the ignition of petroleum gas rising from a petroleum vein in the depth of the mountain.

Apropos of the forthcoming erection of a monument to Sauvage at Boulogne-sur-Mer, it may be mentioned that a rival claim to the invention of the screw propeller has been set up on behalf of a person named Dallery, also a Frenchman, whose granddaughter, it is alleged, has submitted certain evidence to the Académie des Sciences, showing that her grandfather, who died in 1835, took out a patent as long ago as 1813 for certain contrivances, including a screw propeller and a tubular boiler. M. de Lesseps is of opinion that although Dallery, like Pauchon, had long ago conceived the idea of the screw, yet it is to Sauvage that the credit is due of having been the first to apply it to practical purposes.

THE following candidates have been successful in obtaining Royal Exhibitions of 50*l.* per annum each for three years, and free admission to the course of instruction at the following institutions:—1. The Normal School of Science and Royal School of Mines, South Kensington and Jermyn Street, London—Thomas Mather, aged twenty-four, pattern maker, Manchester; Alfred Sutton, twenty-one, engine-fitter, Brighton; William H. Littleton, seventeen, student, Bristol. 2. The Royal College of Science, Dublin—Arthur Whitwell, nineteen, ex-pupil teacher, Nottingham; Frederick J. Willis, eighteen, student Bristol; Christopher J. Whittaker, twenty-one, pattern maker, Accrington.

MR. E. B. TYLOR requests us to mention that the portrait of Andaman Islanders in his "Anthropology," p. 88, which was reproduced in Mr. Wallace's review in NATURE, vol. xxiv. p. 242, is from one of the admirable series of photographs taken in 1872 by Dr. G. E. Dobson, now of the Army Medical School, Netley Hospital. By inadvertence, the cut in question was printed in the "Anthropology" without reference to Dr. Dobson. His paper "On the Andamans and Andamanese" in vol. iv. of the *Journal* of the Anthropological Institute, which gives an account of his visit to the natives in their forest-home, is illustrated with a set of three portrait-groups, which show perfectly their peculiar and homogeneous race-type.

MESSRS. CASSELL AND CO. have issued the first part of "an entirely new and revised edition" of Dr. Robert Brown's "Races of Mankind," under the title of "The Peoples of the World."

PHYLLOXERA has made its appearance in Hungarian vineyards. Its occurrence in the district of Szölös Urdo (Torda Comitat) has been officially stated. Also in the Swiss canton of Neufchâtel it is spreading to an alarming extent. The vineyards of Grand-Saconnex, Colombier, and La Coudre are fast succumbing to the plague.

M. SYNYROS, an Athens merchant, has recently given 100,000 francs for building a museum at Olympia.

THE construction of another great Alpine tunnel which should bring Paris and the North of France into more direct communication with Italy than is afforded by the existing tunnel through Mont Cenis, is under consideration with the French Government, the projects including not only one through Mont Blanc, but also through the Simplon or the Great St. Bernard. It is not likely, however, that the latter will meet with much encouragement. The tunnel under the Simplon would be 60,719 feet long, while that under Mont Blanc is only 44,292

feet. As connected with other Alpine tunnels, Mont Cenis is 40,093 feet, and St. Gothard, 48,952 feet. The Simplon would therefore be longest of all; but, on the other hand, it would be on a lower level than the others, the entrance at Brieg being only 2333 feet, and that at Iselle 2253 feet above the sea level. The entrances to the Mont Blanc tunnel would be 3345 feet at Mont Quart, and 4215 feet at Entrèves above the sea level. The Bardonneche entrance to Mont Cenis is 3970 feet, and that at Modane 3799 feet, while in the case of the St. Gothard tunnel the northern entrance at Göschenen is 3638 feet, and the southern, at Airolo, 3756 feet above the sea. Thus the Mont Cenis tunnel is shorter, but 330 feet higher than the Mont Blanc, while the Simplon would be about half as long again, but about 1000 feet lower. Supposing that the operations would be conducted at the same rate as they have been at St. Gothard, the boring will take 4218 days, or, working at both ends, 2109—nearly six years.

THE additions to the Zoological Society's Gardens during the past week include two Guinea Baboons (*Cynocephalus sphinx*), a Grivet Monkey (*Cercopithecus griseo-viridis*, var.) from West Africa, presented by Mr. Lionel Hart; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by the Rev. George Cuffe; two Arabian Gazelles (*Gazella arabica*), three Domestic Pigeons (*Columba ænas*) from Arabia, presented by Mr. Reginald Zohrab; two Common Squirrels (*Sciurus vulgaris*), British, presented by Lieut.-Col. F. D. Waters, 82nd Regiment; a Collared Peccary (*Dicotyles tajaçu*) from Guiana, presented by Capt. W. F. Wardroper; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. L. H. Haworth; a Cinereous Sea Eagle (*Haliaëtus albicilla*) from Norway, presented by Mr. James Ashbury; a Red and Blue Macaw (*Ara macao*) from South America, presented by Mrs. Supple; two Common Barn Owls (*Strix flammea*), British, presented by Mr. C. T. Foster; an Upland Goose (*Bernicla magellanica*) from South America, presented by Mr. A. Nesbitt; two Common Kestrels (*Tinnunculus alaudarius*), British, presented by Mr. J. Edwards: a Bonnet Monkey (*Macacus radiatus*) from India, a Common Marmoset (*Hapale jacchus*), from South-East Brazil, deposited; two European Scops Owls (*Scops giu*), European, purchased. Amongst the additions to the Insectarium during the same period are larvæ of the Common Butterfly (*Vanessa C. album*), Lobster Moth (*Stauropus fagi*), Pale Tussock Moth (*Orgyia pudibunda*)—the so-called Hop-Dog—*Diphthera orion*, *Halias prasinana*, and *Deilephila euphorbiæ* and *galii*; also a perfect insect of *Cholus forbesi*, being the third known example of this species, originally described from specimens captured in an orchid-house at Highgate. The present specimen was found, under similar conditions, by Dr. Wallace of Colchester.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 22.—M. Jamin in the chair.—The following papers were read:—Meridian observations of small planets and of Comet *b* 1881, at Paris Observatory, during the second quarter of 1881, by M. Mouchez.—Remarks on M. Jamin's note on comets, by M. Faye.—On spectrum analysis applied to comets, by the same.—On the nature of the repulsive force exercised by the sun, by the same. He associated it long ago with the state of incandescence of the sun; and, in an experiment, rare gaseous matter made luminous by means of an induction-spark was repelled by an incandescent plate at a sensible distance. Some thought this not decisive, however; for the gaseous matter might become more conductive through heating, so that the effect observed might be a sort of obscure discharge. M. Faye invites physicists to take up the matter afresh.—On the interior state of the terrestrial globe, by M. Roche. Supposing the globe formed of a nucleus or solid block nearly homogeneous, covered with a lighter layer, of density geologically shown to be about 3 in relation to water; he finds it possible to harmonise the general values of precession and flattening, if it be considered that the interior nucleus has solidified and taken its definitive form under influence of a rotation less rapid than that now animating the earth. The central block is probably like meteoric iron in specific gravity, while the enveloping layer is comparable to aëroliths of stony nature, with little iron.—On the irreducible co-variants of the binary quartic of the eighth order, by Prof. Sylvester.—On a new species of Cissus (*Cissus Rocheana*, Planch), from the interior of Sierra Leone, capable of bearing the winter of Marseilles, by M. Planchon. Its endurance is a matter of temperament, and a proof of the extent of the scale of resistance to cold and heat which some plants possess, and which often upsets all prevision. The American *Vitis riparia* lives sixty miles north of Quebec, and is also found in the sub-tropical Southern States.—On the laws of formation of cometary tails, by M. Schwedoff. Starting with the existence of an infinite number of ponderable particles in celestial space, he shows that those with parabolic orbits have most chance of collision and consequent heating and dispersion. The sudden vaporisation of solids, due to passage among them of a cometary nucleus, generates the cometary nebulosity. The velocity of propagation of visible waves accompanying the nucleus is equal to the velocity of the nucleus itself at the moment of departure of these waves. The maximum of intensity of a cosmic wave is found in the tangent to the orbit of the nucleus at the point of departure of the wave. With these two laws he seeks to explain the phenomena observed.—On a particular case of the theory of motion of an invariable solid in a resistant medium, by M. Willotte.—M. Trève communicated the results of some experiments as to the effects produced by shunts in telephonic circuits.—Solar observations at the Royal Observatory of the Roman College during the first quarter of 1881, by P. Tacchini. After the secondary minimum in the end of last year, the solar activity resumed its course towards the maximum. The distribution of protuberances, &c., was the same as in the last quarter of 1880.—Observations of solar spots and faculæ in April to July, 1881, by P. Tacchini. A minimum of spots occurred in May, and an exceptional maximum in July; now, the activity is anew at a minimum. During this year several periods of abundant frequency have recurred.—Spectroscopic studies on comets *b* and *c* 1881, by M. Thollon. Comet *c* seems to be almost wholly gaseous. The brightness of the head and tail of the comets seems to vary rapidly and uniformly with distance from the sun; arguing that their white light is almost wholly reflected sunlight. The slowness of variation of the band spectrum is against the view that the cometary elements are rendered incandescent by calorific action of the sun. The comets have probably a light and heat of their own.—Researches on the telluric lines of the solar spectrum, by M. Egoroff. Sending a strong electric beam through 18m. of aqueous vapour, and increasing the tension to 6 atm., the spectrum was notably changed in aspect. The group *a* in the extreme red he thinks fundamental for aqueous vapour, and he is going to examine it in detail.—On the existence of a new metallic element, actinium, in the zinc of commerce, by Mr. Phipson.—Note relative to a new series of phosphates and arseniates, by MM. Filhol and Senderens.—Fixation of hypochlorous acids on propargylic compounds, by M. Henry.—On the abnormal presence of uric acid in the salivary, gastric, nasal, pharyngeal, sudoral, and uterine secretions, and in menstrual blood; diagnostic and therapeutic indications, by M. Boucheron.—Observations during a thunderstorm on June 25, 1881, by M. Larroque.

THE STUDENT'S DARWIN

The Student's Darwin. By Edward B. Aveling, D.Sc., Fellow of University College, London. International Library of Science and Freethought. Vol. II. (London: Annie Besant and Charles Bradlaugh, 1881.)

SEVERAL months ago we reviewed the first volume of this series, and now in reviewing the second we are still of opinion that the promoters of the series are mistaken, so far as they may have the interests of science at heart, in associating their endeavours to render science popular with their systematic onslaught against theistic belief. In itself science has no necessary relation to any such belief; it is neither theistic nor atheistic; it is simply extra-theistic. It is but an extension of common experience, and as such has to deal only with the facts of ordinary knowledge without at any point being able to escape from the sphere of the phenomenal; in so far as any inferences are extended from this domain they are not scientific but metaphysical. Therefore, although it may be of use in the interests of "Freethought" to represent science as not merely neutral but negative in its bearings upon religion, the attempt to do so is detrimental to the interests of science; so far as it may be successful it can only tend to increase the suspicious dislike of scientific knowledge which large masses of the general public are already too apt to harbour. Still, as the leading object of the "International Library" is no doubt that of advancing anti-theistic dogma, its promoters are probably careless whether in so doing they are either loyal or just to the cause of science, under whose banner and in whose name they profess to march.

But beyond recording our dissent from the unreasonable and, from our point of view, pernicious association of "Science" with "Freethought" which is being carried through the "International Library," we have nothing further to do with this matter; in these columns we have only to deal with the science, and so shall not again refer to the freethought, although it may be noted as a curious illustration of the contrast between "the solid ground of nature" and the quicksands of speculative thinking, that one of our most recent reviews was that of a book by Dr. Lauder Brunton, who is certainly no less an authority in science than Dr. Aveling, and whose whole object was seen to be the exact reverse of that which appears in "The Student's Darwin,"—viz., to show that Darwinism is *not* opposed to theism. For ourselves, it is needless to add, we hold that the theory of evolution resembles all other scientific theories in having no point of legitimate contact with any ulterior question of metaphysics, further than that of removing from metaphysics certain erroneous arguments previously based upon imperfect knowledge.

Dr. Aveling has been a diligent student of Mr. Darwin's books, and on reading his epitome of them, even in the most cursory way, one is more than ever amazed at the enormous fertility of Mr. Darwin's work. At every page one feels how meagre the epitome is—often little better than an index—and yet for more than 300 pages the index runs on showing as in a sketch what the mind of one man has accomplished, till the reader who is able to remember how many and minute are the details which the index embraces is glad to agree with an introductory remark of the writer, "It is well that all of us should know at least the outline of the work that has been done by this man. For as the name of Chaucer marks the fourteenth, and the name of Shakespeare the sixteenth century, so probably will the name of Charles Darwin mark the nineteenth century in the years to come."

The object of the "Student's Darwin" is thus, as its author says, to furnish a brief summary of the main results of Mr. Darwin's labours, and as the abstract has on the whole been well made, it ought to be found useful for any one who has not time to read for himself the originals. It would have been desirable to have gone less into mere description of species, and more fully into the theory of their origin; for no one who is likely to read the book will profit by the former, while the chief object of the "Student's Darwin" ought to be that of rendering a careful and complete abstract of Darwinism. Yet this is far from being the case in the book before us When, for instance, we have the arguments from Classification, Morphology, Development, and Rudimentary Organs all compressed into less than two pages, it is evident that the analysis is becoming much too scanty; and in fact no one depending for his information upon this analysis alone could form any just idea of the mass of evidence in favour of evolution and natural selection which Mr. Darwin has collected. This fault is the less pardonable, because it cannot be pleaded in excuse for it that the author is pressed for space, seeing that throughout the book he every here and there devotes a paragraph or two to bad attempts at "fine writing," which, besides being blemishes from a literary point of view, absorb a number of pages which might have been profitably devoted to a further exposition of what he properly terms "the *magnum opus*."

Dr. Aveling, however, everywhere exhibits a just estimate of Mr. Darwin's powers, as a few quotations may suffice to show. "From these pages" (*i.e.* those of the Monograph of the Cirripedia) "the student will turn with renewed reverence for the great generaliser, who is so patient and so completely master of detail." "Preconceived notions are not for him. He states the arguments for the conclusions that would strengthen the position of the great theory of evolution only less clearly than he states those that tell against that theory. No man was ever more of judge than he; no man was ever less of advocate. . . . The obligations of Charles Darwin to other workers in the same field as himself are always paid with a cordiality and courtesy that must be as gratifying to them as they are natural to him." "Only thirty-four years and the man who has produced the new thoughts is still among us! To-day they form part of the accepted creed of scientific thinkers. . . . To those who remember how few of the great have beheld with their own patient eyes their own greatness in some faint degree recognised during their own lives, their own thoughts accepted as true guides by the thoughtful, assuredly there is cause for comfort here." "Looking back over them again" (*i.e.* the whole series of works), "we cannot fail to be impressed with those two large attributes of genius that are especially his—unrivalled powers of observation, unrivalled powers of generalisation. And the homage that we pay him

to-day is, I am assured, but the feeblest of utterances as compared with the heartfelt gratitude and wondering praise that will be the reward of this great thinker in those future times when the very lowliest in the land shall have full grasp of the meaning of his teaching," &c.

On the whole, the "Student's Darwin" deserves to be successful in its object of popularising Mr. Darwin's work. The great bar to its usefulness will be its needlessly aggressive tone towards religion, which is sure greatly to lessen a circulation which it might otherwise have had.

GEORGE J. ROMANES

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Tebbutt's Comet—Origination of its Proper Light

WHILE there seems now no doubt that the honour of being the discoverer of the great comet of 1881 belongs without question to that life-long and most persevering observer, as well as successful computer, of comets, in Australia, Mr. John Tebbutt, three communications which chance to have arrived here this morning from different countries contain most diverse ideas of the nature of that portion of the comet's light which universal spectroscopic observation proves is inherent to the comet itself, indicating the existence there of carburetted gas of some kind, and is quite distinct from the concomitant weak reflection of solar light.

1. In Abbé and Chanoine Moigno's *Les Mondes* for August 25, that excellent physicist in Paris, M. Jamin, is represented as stating that the comet's carburetted gas could be rendered "properly" luminous only in two modes, viz., either by combustion or electric discharges. "If by combustion," says he, "how did it first take fire? what keeps up the fire perpetually? and how are the materials of the comet kept, in such a fire, from becoming red-hot, and then giving out quite a different spectrum to any that has yet been observed?" Wherefore he concludes that the cause of the "proper" light of the comet is the illumination of its constituent molecules by electric discharge, as in the gas-vacuum tubes of our laboratories.

2. But next comes a pamphlet from that accomplished spectroscopist and astronomer, Prof. C. A. Young of Princeton, New Jersey, U.S., setting forth that the bands of carburetted gas seen in the comet's spectrum do most admirably and exactly agree with the combustion-bands of coal-gas and air, as seen in a Bunsen-burner or a blowpipe flame, or in the blue base of all carbo-hydrogen flames known; while they do, on the contrary, most eminently, markedly, and distinctly disagree from the bands of the spectra of the same gases as seen in gas vacuum-tubes when illumined by electric discharge. And this conclusion of the eminent American physicist is confirmed by a pamphlet just received from M. Fiévez, the spectroscopic observer of the re-organised Royal Observatory of Brussels; as was also announced at the very time of the comet's appearance by the present most acutely observing Astronomer-Royal at Greenwich.

3. What then! Is M. Jamin's theory of the comet's proper light being entirely due to electrical illumination utterly overthrown, and the celestial phenomenon given over to a process of combustion, the mere mention of the necessary details of which suffices to show it ridiculous and impossible?

4. Not yet, I venture to think. We ought to discriminate in such a case most carefully between electricities of different intensities and different temperatures. Something too of that kind, and even much to the purpose of this cometary case, I had the honour of setting forth to the Royal Society, Edinburgh, last year, in a paper which is now being printed for their *Transactions*. For it was shown therein that, when using an induction-coil capable of giving sparks of such intensity as to be five inches long in the open air, a gas vacuum-tube of olefiant gas showed only the carburetted bands which Prof. Young alludes to as being absolutely *not* the bands which the spectrum of the comet exhibited. But when a smaller coil was employed, and more particularly when its outer helix of long thin wire was replaced by another of short thick wire (specially prepared for the experiment), and the sparks thereby lowered in intensity to such a degree as from 1·3 of an inch, to be capable of only passing through 0·2 inch of air, then, when employed to illuminate the same olefiant gas vacuum-tube, besides the bands seen before (but now more faintly), another set of bands appeared, which were exactly those of the combustion of coal-gas and air, of Bunsen burners, blowpipe flames, blue base of all carbo-hydrogen flames, and finally—*teste* Prof. C. A. Young, M. Fiévez, the Astronomer-Royal, W. H. M. Christie, and others—of Tebbutt's great comet of 1881.

5. From this condensation of testimonies I presume that no other conclusion is to be drawn than that the electrical discharges permeating the whole length of a comet's tail must be something exceedingly weak in intensity;—and the gentlemen who employ electrically lit-up gas vacuum-tubes in their laboratories must do their spiriting with them in future much more gently, if they would really arrive at what goes on in cometary existences. The following exception, too, duly mentioned by Prof. Young, to his general rule, seems to tend in the same direction. For he states "that while the evidence as to the identity of the flame and comet spectra is almost overwhelming, the peculiar ill-defined appearance of the cometary bands at the time of the comet's greatest brightness is, however, something which he has not yet succeeded in imitating with the flame spectrum."

6. "Certainly not," we may add to this most honest confession; for as the comet's greater brightness near its perihelion passage could hardly be due to anything else than a temporary increase in the intensity of its illuminating electric currents, that would tend to bring out the *tube-set* of carburetted bands to interfere with, and spoil the neatness and sharpness of, the so-called *flame*-bands, and would certainly imply a quality or temperature which does not exist in any known simple flame, but is found in the spark of even the smallest induction coil, unless some special means are taken to damp down its intensity.

I have long wished at this Observatory to try a whole course of electric illuminations, as of the old friction machine, Holtz's machine, modern dynamo-machine, coils in variety, and whatever is capable of giving out electricity in any visible luminous shape; but the state of miserable starvation in which this Royal Observatory, Edinburgh, is kept throughout all its branches by Government, and their continued neglect of the applications of their own "Board of Visitors" to "endeavour to obtain justice to this Observatory"—the very words of the last public remit from the Board-meeting, of which the venerable Duncan McLaren, then M.P. for Edinburgh, was chairman—prevent any important apparatus being purchased, or even obtained on loan, to prosecute the inquiries which the science of the times demands.

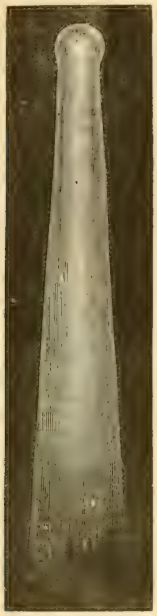
PIAZZI SMYTH,
Astronomer-Royal for Scotland

Royal Observatory, Edinburgh, August 29

Schaeberle's Comet

SINCE my last remarks I have had an opportunity to examine this fine object with the 6″ Cooke equatorial. On Wednesday evening, the 24th, simultaneously with the Great Bear stars, it was easily seen as soon as twilight set in, near the horizon and considerably more to the west than on the 21st. With a comet eyepiece it presented, in spite of its low altitude, a sharp and well-defined figure. The nucleus was stellar-like, with, I thought, a still brighter minute central point. No jets of light proceeded directly from it, but it appeared surrounded by a circular nebulosity of greater extent than the base of the tail, and giving the headed form to the comet frequently seen in old drawings of these objects. The tail was straight, long, and luminous, with a central ray of condensed light which gave it a cylindrical look. When first examined three small stars were involved in the tail without any apparent diminishing of their brightness; while two others below served to define the limit of the tail's visibility in the comet eyepiece. This measured two degrees only, but both it and the nucleus were of a peculiarly fine pale blue tint. I send a drawing of the telescopic appearance of the comet at 8h. 40m. On the nights of the 27th and 28th the comet was again examined at about 8h. 30m. Under a lower power Kellner the appearance was that of a round comet with a central

nucleus and circular coma. The tail was to be seen, but was quite faint, and as before was less at the base than the width of



Sketch of Schaeberle's Comet, August 24, 8h. 40m. in 6″ Cooke equatorial.

the coma. Dr. de Konkoly I see has examined the spectrum of this comet, and found it a faint continuous one, with three tolerably bright lines, at following positions :—

		Estimated brightness.
I.	5601 ± 2·5	0·4
II.	5161 ± 0·9	1·0
III.	4753 ± 0·6	0·8

Schaeberle's Comet, August 28, 8h. 32m.

The appearance of this comet throughout has been peculiarly distinguished from that class in which jets of light streaming from the nucleus in front fall back to form the tail or a brigh margin to it. These, as far as I have seen, have been absent.

Guildown, August 31 J. Rand Capron

Comet *b* 1881

M. Ch. Fievez, the Astronomer adjoint at the Royal Observatory, Brussels, has been good enough to send me a copy of his note on the analysis of the light of this comet, made with the 15-inch Merz-Cooke equatorial, provisionally installed at the Avenue Cortenberg. The polariscopic observations demonstrate that the polarisation of the nucleus was strong (très nette et bien accentuée), while that of the tail was very weak. These observations were made at several days interval, from 11h. till midnight. Sky polarisation was scarcely sensible. The spectroscopic observations proved the spectrum of the comet to consist of four bands of intensity in the following order: green, blue, violet, and yellow, with wave-lengths 5160, 4780, 4200 (about), and 5620. The original appearance of these bands was modified as the comet receded from the sun, their edges towards the red then becoming more and more defined. The nucleus presented a brilliant continuous spectrum, in which however the Fraunhofer lines were not recognised. The conclusions arrived at by M. Fievez were as follows :—That a great part of the light of the comet was inherent to it, while the other part was reflected solar light. That the strong polarisation of the nucleus indicated a marked state of condensation of the matter composing it. That the spectrum differed little from that of other comets. Lastly, that the marked modifications in the brilliancy of the continuous spectrum, and in the appearance of the spectrum bands indicated a progressive diminution in the comet's temperature. The chief interest in the above observations attaches to the feeble polarisation detected in the tail as compared with that found by Prof. A. W. Wright and Mr. Cowper Ranyard, and in the absence of the Fraunhofer lines, which were measured by Dr. N. de Konkoly, and also photographed by Dr. Huggins. Whence, we may ask, arises the divergence of conclusions arrived at by M. Fievez and Prof. Wright respectively, the one considering that the principal part of the comet's light is from itself, the other that it is reflected sunlight, and why were the Fraunhofer lines seen in the one case, and not in the other? The answer lies, I think, not with the instruments employed, but rather in the interesting probability of change in the comet's structure or condition during the time of its examination. A comparison of the many observations recorded during its stay with us may possibly lead to important discoveries in this direction. I am much interested to see that Prof. C. A. Young informs us that the green band was seen by observers at Princeton split up into fine sharp lines coinciding with those seen in the flame spectrum, a result to be expected, but hitherto not attained. J. Rand Capron

Guildown, September 3

The comet at present visible was examined by me with the spectroscope on the 8¼-inch refractor on Saturday evening, August 27. The three principal hydrocarbon bands were plainly visible, the central one being the brightest, and on comparing them with the spectrum of a spirit-lamp flame the coincidence of the least refrangible sides of the bands in the two spectra was sensibly complete. The nucleus gave a narrow continuous spectrum, and I could see no trace of such a spectrum except from that point. I could see no other band in the spectrum except the three above mentioned, but the proximity of the comet to the horizon may have something to do with this.

George M. Seabroke

Temple Observatory, Rugby, August 29

A Pink Rainbow

I spent Sunday, August 21, at Mr. Tennyson's house, Aldworth, near Haslemere. The house stands on an elevated ledge of the Blackdown range, looking over the Weald towards the Brighton Downs, between east and south-east. About sunset the deep red of the south-eastern sky attracted our attention, and while we were looking at it we saw stretching across it a well-marked rainbow, but of a uniform red or pink colour, which Mrs. Tennyson compares, in a note I have just had from her, to a "pink postage-stamp"—not the one now in use, but the last discarded one. This was seen distinctly by Mrs. Tennyson, Mr. Hallam Tennyson, and myself for, I think, more than a minute. Mr. Hallam went to call his father, who was in another room,

but before he came, "the bow," to quote Mr. Tennyson's words, "had assumed its usual colours, which were, however, very faint." Mrs. Tennyson says the pink colour "was visible for a very little time just at sunset, and then I saw a dull olive green at the lower edge." After that, as Mr. Tennyson says, we all saw the vanishing ghost, as it were, of an ordinary rainbow. The actual uniform redness came just at sunset, as marked in the almanac we consulted—ten minutes past seven. A. M.

August 26

The Glacial Period

PLEASE correct an error in the notice of my paper on the Glacial Period (NATURE, vol. xxiv. p. 364). It is on the western slope of New Zealand that the glaciers reach to the highest mean annual temperature (10° C., or 50° F.) as well as to the lowest level. *Apropos* of my studies on this subject, I should be very glad to meet some of the British glacialists at Venice, at the third International Geographical Congress, and discuss some points of interest with them. As there is, a few days later, an International Geological Congress at Bologna, it will be the easier for geologists to make a short stay at Venice before. The Geographical Congress begins on September 15.

St. Petersburg, August 13–25 A. WOEIKOF

THE BRITISH ASSOCIATION

THE Jubilee Meeting of the British Association has come to a close, and whether we take the test of work done, or of the numbers present as members or associates, it must be admitted that it has been a great success. While in 1879, in the densely populated town of Sheffield, the total was 1404, and at Swansea last year 915, the number has risen this year to 2533, which includes 22 foreign members, 510 ladies, and 1173 associates. Of course York does not supply the whole of the latter: many come from Leeds, Sheffield, and Scarborough, and the surrounding towns. Seven times previously has the number been greater; the maximum (3335) having been attained at Newcastle-on-Tyne in 1863. As regards work done, it may be mentioned that on Friday nearly a hundred papers were announced for reading in the various sections. One of the laws of the Jewish jubilee festival was that the land should remain untilled for a year; but we have reversed this, and only cultivated our scientific soil the more. Sir David Brewster, in the original letter which laid the foundations of the society, suggested York as the most central city of the three kingdoms, but he first inquired "if York will furnish the accommodation necessary for so large a meeting, which might perhaps consist of 100 individuals." Apparently therefore he did not contemplate the admission of associates, or the use of the Association as a means of scattering broadcast the results of the scientific year, but rather regarded it as a means whereby the cultivators of science might become better acquainted with each other at a time when communication with London was far more difficult, and intercourse through scientific publications far more restricted than now. But the first meeting numbered 350 members, and included some of the most representative men of science of the day. On this occasion the presidential address lasted five minutes.

The proceedings commenced on Wednesday, August 31, by the reading of the Report of the Council, in which it was announced that Mr. P. L. Sclater had resigned the office of general secretary, and that he would be succeeded by Mr. F. M. Balfour of Cambridge. Mr. G. E. Gordon has also retired from the assistant secretaryship, and is to be succeeded by Prof. Bonney, with the title of secretary and a salary of 300*l.* per annum, with 25*l.* for travelling expenses. Mr. Spottiswoode succeeds Sir Philip de Malpas Grey Egerton as trustee.

The new members of council are Messrs. Warren De La Rue, A. Vernon Harcourt, G. W. Hastings, J. C. Hawkshaw, and G. Prestwich.

Sir John Lubbock's address was listened to by a very crowded audience. The Exhibition Hall is a fine building, and was prettily decorated, but its acoustic properties are somewhat deficient, and the unsteady electric light was painful to the eyes. The address occupies fifty octavo pages, of which nearly twenty were omitted during delivery. On the subject of education the President expressed himself strongly; he asked that more time should be given to French, German, science, and mathematics. "What we ask is that, say, six hours a week each should be devoted to mathematics, modern languages, and science, an arrangement which would still leave twenty hours for Latin and Greek"; and he added, "we cannot but consider that our present system of education is, in the words of the Duke of Devonshire's Commission, little less than a national misfortune."

Sir John Lubbock adopted a judicious mean between the address devoted entirely to one subject on the one hand, and giving a general *résumé* of the progress of all the sciences on the other; for while he spoke in detail and authoritatively concerning the biological sciences, he also furnished accounts of the progress of the physical sciences, prepared by men well competent to discuss them.

The Section work began in earnest on Thursday morning. Some idea of the number of representative men who were present at the meeting may be gathered from the fact that in Section A there are ten vice-presidents and fifty-seven members of committee, and these numbers are exceeded in some of the sections; so that there are more than fifty vice-presidents of sections, and more than three hundred members of sectional committees. The sections were housed in capacious and very suitable rooms, and the attendance was very good.

The loan collection of scientific apparatus, although it contained some very interesting examples, was by no means a collection which represents the experimental progress of the last fifty years, and the appeal for historical apparatus has scarcely been responded to. The exhibition was shown at the Thursday *soirée*, and remained open till the end of the week of meeting. A good catalogue of thirty-two pages was prepared. We may particularly notice some beautifully-finished telescopes and transit instruments, and an electric chronograph exhibited by Messrs. T. Cooke and Sons; a model of the Vienna 27-inch refractor and its dome by Mr. Howard Grubb; and a very old telescope constructed by Abraham Sharp. The Manchester Literary and Philosophical Society exhibited some of the apparatus used by John Dalton in his researches; and the Science and Art Department sent astrolabes and sun-dials of the sixteenth, seventeenth, and eighteenth centuries. A few instruments were sent by foreign makers. Dr. Stone exhibited a large syren fitted with a key-board and worked at an uniform rate by clockwork. A quantity of physiological apparatus was exhibited by Dr. Burdon-Sanderson and Mr. G. B. Thistleton. Mr. Francis Galton exhibited and explained his composite photographic process, "a method of superposing the images of separate portraits and thence creating a face, the sum of all the components employed; it has a curious air of individuality about it, but is a perfectly ideal face, like all, but exactly resembling none." Dr. Tempest Anderson, one of the local secretaries, exhibited some ophthalmic appliances. The North-Eastern Railway Company exhibited an interesting meteorite which fell on March 14 last between the Middlesbrough and Ormesby stations of the Guisborough line. It is of the stony tufaceous type, and weighs three and a half pounds.

On Friday afternoon several manufactories were visited, also the gas-works and water-works. Messrs. Cooke's works were of especial interest, particularly the processes connected with the grinding of lenses and the graduation of circles by means of a large dividing-engine, the great circle of which is marked with divisions, each of which is

equal to five minutes of arc. Saturday afternoon was as usual devoted to excursions, but the steady downpour of rain did much to mar the enjoyment. Several people in the vicinity of York have entertained the members very hospitably, and have thrown open their houses. On Monday the usual meteorological breakfast took place; forty persons were present, and meteorology was the chief order of the day in Section A. In the evening Mr. Spottiswoode gave a discourse on "The Electric Discharge." The Red Lion Club met on Tuesday before the *soirée*.

Southampton has been chosen as the place of meeting in 1882, and Dr. C. W. Siemens has been elected president. A vigorous contest for the honour of receiving the Association took place yesterday between six towns:—Leicester, Nottingham, Southport, Oxford, Birmingham, and Aberdeen. The claims of each town were stated by delegates, and afterwards votes were taken by a show of hands. Birmingham withdrew. The President of the Royal Society, Sir Joseph Hooker, and Professors Acland, H. J. S. Smith, and Prestwich, strongly advocated the claims of Oxford, and the show of hands was declared to be in its favour. Southport was second on the list. Worcester has lodged a claim for 1884.

Altogether more than three hundred papers or reports have been read.

Eighteen papers were put on the list of Section A for Tuesday; twenty-eight in the Geological Section, thirteen in that of Anthropology, and fifteen in Mechanical Science. Thus the work has never flagged at all.

At the Committee Meeting on Wednesday Capt. Bedford Pim gave notice of motion that the meeting be held in Canada in 1885.

The following grants have been made:—

	£
The Council—Exploration of Mountain District of Eastern Equatorial Africa	100
A—Mathematics and Physics	
Mr. G. H. Darwin—Lunar Disturbance of Gravity	15
Dr. A. Schuster—Meteoric Dust	20
Prof. Sylvester—Fundamental Invariants (partly renewed)	80
Mr. R. H. Scott—Synoptic Charts of the Indian Ocean	50
Prof. G. C. Foster—Standards for Use in Electrical Measurements (partly renewed)	100
B—Chemistry	
Prof. Dewar—Present State of Knowledge of Spectrum Analysis	5
Prof. Balfour Stewart—Calibration of Mercurial Thermometers	20
Prof. Roscoe—Wave-lengths Tables of Spectra of Elements	50
Dr. Hugo Müller—Chemical Nomenclature	10
Prof. Odling—Photographing the Ultra-Violet Spark Spectra	25
C—Geology	
Dr. J. Evans—Record of the Progress of Geology	100
Prof. Ramsay—Earthquake Phenomena of Japan	25
Dr. H. C. Sorby—Conditions of Conversion of Sedimentary Materials into Metamorphic Rocks	10
Prof. W. C. Williamson—Fossil Plants of Halifax	15
Dr. Sorby—Conversion of Sediments into Metamorphic Rocks	10
Prof. A. C. Ramsay—Geological Map of Europe	25
Prof. E. Hull—Circulation of Underground Waters	15
Prof. W. C. Williamson—Tertiary Flora associated with the Basalts of the North of Ireland	20
Dr. Sorby—British Fossil Polyzoa	10
Prof. Leith-Adams—Carboniferous Limestone Caves in South Ireland	10
Prof. Green—Exploration of Raygill Fissure	20
D—Biology	
Mr. F. M. Balfour—Table at the Zoological Stations at Naples	80

SECTION A

MATHEMATICAL AND PHYSICAL

OPENING ADDRESS BY SIR WILLIAM THOMSON, F.R.S., PROFESSOR OF NATURAL PHILOSOPHY IN THE UNIVERSITY OF GLASGOW, PRESIDENT OF THE SECTION

On the Sources of Energy in Nature Available to Man for the Production of Mechanical Effect

DURING the fifty years' life of the British Association, the Advancement of Science for which it has lived and worked so well has not been more marked in any department than in one which belongs very decidedly to the Mathematical and Physical Section—the science of Energy. The very name energy, though first used in its present sense by Dr. Thomas Young about the beginning of this century, has only come into use practically after the doctrine which defines it had, during the first half of the British Association's life, been raised from a mere formula of mathematical dynamics to the position it now holds of a principle pervading all nature and guiding the investigator in every field of science.

A little article communicated to the Royal Society of Edinburgh a short time before the commencement of the epoch of energy under the title "On the Sources Available to Man for the Production of Mechanical Effect"[1] contained the following:—

"Men can obtain mechanical effect for their own purposes by working mechanically themselves, and directing other animals to work for them, or by using natural heat, the gravitation of descending solid masses, the natural motions of water and air, and the heat, or galvanic currents, or other mechanical effects produced by chemical combination, but in no other way at present known. Hence the stores from which mechanical effect may be drawn by man belong to one or other of the following classes:—

"I. The food of animals.

"II. Natural heat.

"III. Solid matter found in elevated positions.

"IV. The natural motions of water and air.

"V. Natural combustibles (as wood, coal, coal-gas, oils, marsh-gas, diamond, native sulphur, native metals, meteoric iron).

"VI. Artificial combustibles (as smelted or electrically-deposited metals, hydrogen, phosphorus).

"In the present communication, known facts in natural history and physical science, with reference to the sources from which these stores have derived their mechanical energies, are adduced to establish the following general conclusions:—

"1. *Heat radiated from the sun* (sunlight being included in this term) *is the principal source of mechanical effect available to man*.[2] From it is derived the whole mechanical effect obtained by means of animals working, water-wheels worked by rivers, steam-engines, galvanic engines, windmills, and the sails of ships.

"2. The motions of the earth, moon, and sun, and their mutual attractions, constitute an important source of available mechanical effect. From them all, but chiefly no doubt from the earth's motion of rotation, is derived the mechanical effect of water-wheels driven by the tides.

"3. The other known sources of mechanical effect available to man are either terrestrial—that is, belonging to the earth, and available without the influence of any external body—or meteoric—that is, belonging to bodies deposited on the earth from external space. Terrestrial sources, including mountain quarries and mines, the heat of hot springs, and the combustion of native sulphur, perhaps also the combustion of inorganic native combustibles, are actually used, but the mechanical effect

[1] Read at the Royal Society of Edinburgh on February 2, 1852 (*Proceedings* of that date).

[2] A general conclusion equivalent to this was published by Sir John Herschel in 1833. See his "Astronomy," edit. 1849, § (399).

obtained from them is very inconsiderable, compared with that which is obtained from sources belonging to the two classes mentioned above. Meteoric sources, including only the heat of newly-fallen meteoric bodies, and the combustion of meteoric iron, need not be reckoned among those available to man for practical purposes."

Thus we may summarise the natural sources of energy as Tides, Food, Fuel, Wind, and Rain.

Among the practical sources of energy thus exhaustively enumerated, there is only one not derived from sun-heat—that is the tides. Consider it first. I have called it *practical*, because tide-mills exist. But the places where they can work usefully are very rare, and the whole amount of work actually done by them is a drop to the ocean of work done by other motors. A tide of two metres' rise and fall, if we imagine it utilised to the utmost by means of ideal water-wheels doing with perfect economy the whole work of filling and emptying a dock-basin in infinitely short times at the moments of high and low water, would give just one metre-ton per square metre of area. This work done four times in the twenty-four hours amounts to 1-1620th of the work of a horse power. Parenthetically, in explanation, I may say that the French metrical equivalent (to which in all scientific and practical measurements we are irresistibly drawn, notwithstanding a dense barrier of insular prejudice most detrimental to the islanders),—the French metrical equivalent of James Watt's "horse-power" of 550 foot-pounds per second, or 33,000 foot-pounds per minute, or nearly two million foot-pounds per hour, is 75 metre-kilogrammes per second, or 4½ metre-tons per minute, or 270 metre-tons per hour. The French ton of 1000 kilogrammes used in this reckoning is 0·984 of the British ton.

Returning to the question of utilising tidal energy, we find a dock area of 162,000 square metres (which is a little more than 400 metres square) required for 100 horse-power. This, considering the vast costliness of dock construction, is obviously prohibitory of every scheme for economising tidal energy by means of artificial dock-basins, however near to the ideal perfection might be the realised tide-mill, and however convenient and non-wasteful the accumulator—whether Faure's electric accumulator, or other accumulators of energy hitherto invented or to be invented—which might be used to store up the energy yielded by the tide-mill during its short harvests about the times of high and low water, and to give it out when wanted at other times of the six hours. There may however be a dozen places possible in the world where it could be advantageous to build a sea-wall across the mouth of a natural basin or estuary, and to utilise the tidal energy of filling it and emptying it by means of sluices and water-wheels. But if *so* much could be done, it would in many cases take only a little more to keep the water out altogether, and make fertile land of the whole basin. Thus we are led up to the interesting economical question, whether is forty acres (the British *agricultural* measure for the area of 162,000 square metres) or 100 horse-power more valuable. The annual cost of 100 horse-power night and day, for 365 days of the year, obtained through steam from coals, may be about ten times the rental of forty acres at 2*l.* or 3*l.* per acre. But the value of land is essentially much more than its rental, and the rental of land is apt to be much more than 2*l.* or 3*l.* per acre in places where 100 horse-power could be taken with advantage from coal through steam. Thus the question remains unsolved, with the possibility that in one place the answer may be *one hundred horse-power*, and in another *forty acres*. But, indeed, the question is hardly worth answering, considering the rarity of the cases, if they exist at all, where embankments for the utilisation of tidal energy are practicable.

Turning now to sources of energy derived from sun-heat, let us take the wind first. When we look at the register of British shipping and see 40,000 vessels, of which about 10,000 are steamers and 30,000 sailing ships, and when we think how vast an absolute amount of horse-power is developed by the engines of those steamers, and how considerable a proportion it forms of the whole horse-power taken from coal annually in the whole world at the present time, and when we consider the sailing ships of other nations, which must be reckoned in the account, and throw in the little item of windmills, we find that, even in the present days of steam ascendency, old-fashioned Wind still supplies a large part of all the energy used by man. But however much we may regret the time when Hood's young lady, visiting the fens of Lincolnshire at Christmas, and writing to her dearest friend in London (both sixty years old now if they are alive), describes the delight of sitting in a bower and looking over the wintry plain, not desolate, because "windmills lend revolving animation to the scene," we cannot shut our eyes to the fact of a lamentable decadence of wind-power. Is this decadence permanent, or may we hope that it is only temporary? The subterranean coal-stores of the world are becoming exhausted surely, and not slowly, and the price of coal is upward bound—upward bound on the whole, though no doubt it will have its ups and downs in the future as it has had in the past, and as must be the case in respect to every marketable commodity. When the coal is all burned; or, long before it is all burned, when there is so little of it left and the coal-mines from which that little is to be excavated are so distant and deep and hot that its price to the consumer is greatly higher than at present, it is most probable that windmills or wind-motors in some form will again be in the ascendant, and that wind will do man's mechanical work on land at least in proportion comparable to its present doing of work at sea.

Even now it is not utterly chimerical to think of wind superseding coal in some places for a very important part of its present duty—that of giving light. Indeed, now that we have dynamos and Faure's accumulator, the little want to let the thing be done is cheap windmills. A Faure cell containing 20 kilogrammes of lead and minium charged and employed to excite incandescent vacuum-lamps has a light-giving capacity of 60-candle hours (I have found considerably more in experiments made by myself; but I take 60 as a safe estimate). The charging may be done uninjuriously, and with good dynamical economy in any time from six hours to twelve or more. The drawing-off of the charge for use may be done safely, but somewhat wastefully, in two hours, and very economically in any time of from five hours to a week or more. Calms do not last often longer than three or four days at a time. Suppose then that a five days storage-capacity suffices (there may be a little steam-engine ready to be set to work at any time after a four-days' calm, or the user of the light may have a few candles or oil-lamps in reserve, and be satisfied with them when the wind fails for more than five days). One of the twenty kilogramme cells charged when the windmill works for five or six hours at any time, and left with its 60 candle-hours' capacity to be used six hours a day for five days, gives a 2-candle light. Thus thirty-two such accumulator cells so used would give as much light as four burners of London 16-candle gas. The probable cost of dynamo and accumulator does not seem fatal to the plan, if the windmill could be had for something comparable with the prime cost of a steam-engine capable of working at the same horse-power as the windmill when in good action. But windmills as hitherto made are very costly machines, and it does not seem probable that, without inventions not yet made, wind can be economically used to give light in any considerable class of cases, or to put energy into store for work of other kinds.

Consider, lastly, rain-power. When it is to be had in places where power is wanted for mills or factories of any kind, water-power is thoroughly appreciated. From time immemorial, water-motors have been made in large variety for utilising rain-power in the various conditions in which it is presented, whether in rapidly-flowing rivers, in natural waterfalls, or stored at heights in natural lakes or artificial reservoirs. Improvements and fresh inventions of machines of this class still go on, and some of the finest principles of mathematical hydrodynamics have, in the lifetime of the British Association, and, to a considerable degree, with its assistance, been put in requisition for perfecting the theory of hydraulic mechanism and extending its practical applications.

A first question occurs: Are we necessarily limited to such natural sources of water-power as are supplied by rain falling on hill-country, or may we look to the collection of rain-water in tanks placed artificially at sufficient heights over flat country to supply motive power economically by driving water-wheels? To answer it: Suppose a height of 100 metres, which is very large for any practicable building, or for columns erected to support tanks; and suppose the annual rainfall to be three-quarters of a metre (30 inches). The annual yield of energy would be 75 metre-tons per square metre of the tank. Now one horse-power for 365 times 24 hours is 236,500 foot-tons; and therefore (dividing this by 75) we find 3153 square metres as the area of our supposed tank required for a continuous supply of one horse-power. The prime cost of any such structure, not to speak of the value of the land which it would cover, is utterly prohibitory of any such plan for utilising the motive power of

rain. We may or may not look forward hopefully to the time when windmills will again "lend revolving animation" to a dull flat country; but we certainly need not be afraid that the scene will be marred by forests of iron columns taking the place of natural trees, and gigantic tanks overshadowing the fields and blackening the horizon.

To use rain-power economically on any considerable scale we must look to the natural drainage of hill country and take the water where we find it either actually falling or stored up and ready to fall when a short artificial channel or pipe can be provided for it at moderate cost. The expense of aqueducts, or of underground water-pipes, to carry water to any great distance—any distance of more than a few miles or a few hundred yards—is much too great for economy when the yield to be provided for is *power*; and such works can only be undertaken when the *water itself* is what is wanted. Incidentally, in connection with the water supply of towns, some part of the energy due to the head at which it is supplied may be used for power. There are however but few cases (I know of none except Greenock) in which the energy to spare over and above that devoted to bringing the water to where it is wanted, and causing it to flow fast enough for convenience at every opened tap in every house or factory, is enough to make it worth while to make arrangements for letting the water-power be used without wasting the water-substance. The cases in which water-power is taken from a town supply are generally very small, such as working the bellows of an organ, or "hair-brushing by machinery," and involve simply throwing away the used water. The cost of energy thus obtained must be something enormous in proportion to the actual quantity of the energy, and it is only the smallness of the quantity that allows the convenience of having it when wanted at any moment, to be so dearly bought.

For anything of great work by rain-power, the water-wheels must be in the very place where the water supply with natural fall is found. Such places are generally far from great towns, and the time is not yet come when great towns grow by natural selection beside waterfalls, for power; as they grow beside navigable rivers, for shipping. Thus hitherto the use of water-power has been confined chiefly to isolated factories which can be conveniently placed and economically worked in the neighbourhood of natural waterfalls. But the splendid suggestion made about three years ago by Mr. Siemens in his presidential address to the Institution of Mechanical Engineers, that the power of Niagara might be utilised, by transmitting it electrically to great distances, has given quite a fresh departure for design in respect to economy of rain-power. From the time of Joule's experimental electromagnetic engines developing 90 per cent. of the energy of a Voltaic battery in the form of weights raised, and the theory of the electromagnetic transmission of energy completed thirty years ago on the foundation afforded by the train of experimental and theoretical investigations by which he established his dynamical equivalent of heat in mechanical, electric, electro chemical, chemical, electro-magnetic, and thermo-elastic phenomena, it had been known that potential energy from any available source can be transmitted electromagnetically by means of an electric current through a wire, and directed to raise weights at a distance, with unlimitedly perfect economy. The first large-scale practical application of electro-magnetic machines was proposed by Holmes in 1854, to produce the electric light for lighthouses, and persevered in by him till he proved the availability of his machine to the satisfaction of the Trinity House and the delight of Faraday in trials at Blackwall in April, 1857, and it was applied to light the South Foreland lighthouse on December 8, 1858. This gave the impulse to invention; by which the electro-magnetic machine has been brought from the physical laboratory into the province of engineering, and has sent back to the realm of pure science a beautiful discovery, that of the fundamental principle of the dynamo, made triply and independently, and as nearly as may be simultaneously in 1867 by Dr. Werner Siemens, Mr. S. A. Varley, and Sir Charles Wheatstone; a discovery which constitutes an electro-magnetic analogue to the fundamental electrostatic principle of Nicholson's revolving doubler, resuscitated by Mr. C. F. Varley in his instrument "for generating electricity" patented in 1860; and by Holtz in his celebrated electric machine; and by myself in my "replenisher" for multiplying and maintaining charges in Leyden jars for heterostatic electrometers, and in the electrifier for the siphon of my recorder for submarine cables.

The dynamos of Gramme and Siemens, invented and made in the course of these fourteen years since the discovery of the fundamental principle, give now a ready means of realising economically on a large scale for many important practical applications, the old thermo-dynamics of Joule in electro-magnetism; and, what particularly concerns us now in connection with my present subject, they make it possible to transmit electro-magnetically the work of waterfalls through long insulated conducting wires, and use it at distances of fifties or hundreds of miles from the source, with excellent economy—better economy, indeed, in respect to proportion of energy used to energy dissipated than almost anything known in ordinary mechanics and hydraulics for distances of hundreds of yards instead of hundreds of miles.

In answer to questions put to me in May, 1879,[1] by the Parliamentary Committee on Electric Lighting, I gave a formula for calculating the amount of energy transmitted, and the amount dissipated by being converted into heat on the way, through an insulated copper conductor of any length, with any given electromotive force applied to produce the current. Taking Niagara as example, and with the idea of bringing its energy usefully to Montreal, Boston, New York, and Philadelphia, I calculated the formula for a distance of 300 British statute miles (which is greater than the distance of any of those four cities from Niagara, and is the radius of a circle covering a large and very important part of the United States and British North America), I found almost to my surprise that even with so great a distance to be provided for, the conditions are thoroughly practicable with good economy, all aspects of the case carefully considered. The formula itself will be the subject of a technical communication to Section A in the course of the Meeting on which we are now entering. I therefore at present restrict myself to a slight statement of results.

1. Apply dynamos driven by Niagara to produce a difference of potential of 80,000 volts between a good earth-connection and the near end of a solid copper wire of half an inch (1·27 centimetres) diameter, and 300 statute miles (483 kilometres) length.

2. Let resistance by driven dynamos doing work, or by electric lights, or, as I can now say, by a Faure battery taking in a charge, be applied to keep the remote end at a potential differing by 64,000 volts from a good earth-plate there.

3. The result will be a current of 240 webers through the wire taking energy from the Niagara end at the rate of 26,250 horse-power, losing 5250 (or 20 per cent.) of this by the generation and dissipation of heat through the conductor and 21,000 horse-power (or 80 per cent. of the whole) on the recipients at the far end.

4. The elevation of temperature above the surrounding atmosphere, to allow the heat generated in it to escape by radiation and be carried away by convection is only about 20° Centigrade; the wire being hung freely exposed to air like an ordinary telegraph wire supported on posts.

5. The striking distance between flat metallic surfaces with difference of potentials of 80,000 volts (or 5,000 Daniell's) is (Thomson's "Electrostatics and Magnetism," § 340) only 18 millimetres, and therefore there is no difficulty about the insulation.

6. The cost of the copper wire, reckoned at 8*d.* per lb., is 37,000*l.*; the interest on which at 5 per cent. is 1900*l.* a year. If 5250 horse-power at the Niagara end costs more than 1900*l.* a year, it would be better economy to put more copper into the conductor; if less, less. I say no more on this point at present, as the economy of copper for electric conduction will be the subject of a special communication to the Section.

I shall only say in conclusion that one great difficulty in the way of economising the electrical transmitting power to great distances (or even to moderate distances of a few kilometres) is now overcome by Faure's splendid invention. High potential, as Siemens, I believe, first pointed out, is the essential for good dynamical economy in the electric transmission of power. But what are we to do with 80,000 volts when we have them at the civilised end of the wire? Imagine a domestic servant going to dust an electric lamp with 80,000 volts on one of its metals! Nothing above 200 volts ought on any account ever to be admitted into a house or ship or other place where safeguards against accident cannot be made absolutely and for ever trustworthy against all possibility of accident. In an electric workshop 80,000 volts is no more dangerous than a circular saw.

[1] Printed in the Parliamentary Blue Book Report of the Committee on Electric Lighting, 1879.

Till I learned Faure's invention I could but think of step-down dynamos, at a main receiving-station, to take energy direct from the electric main with its 80,000 volts, and supply it by secondary 200 volt dynamos or 100 volt dynamos, through proper distributing wires, to the houses and factories and shops where it is to be used for electric lighting, and sewing-machines, and lathes, and lifts, or whatever other mechanism wants driving power. Now the thing is to be done much more economically, I hope, and certainly with much greater simplicity and regularity, by keeping a Faure battery of 40,000 cells always being charged direct from the electric main, and applying a methodical system of removing sets of 50, and placing them on the town-supply circuits, while other sets of 50 are being regularly introduced into the great battery that is being charged, so as to keep its number always within 50 of the proper number, which would be about 40,000 if the potential at the emitting end of the main is 80,000 volts.

SECTION D

BIOLOGY

Department of Anthropology

Opening Address by Prof. W. H. Flower, LL.D., F.R.S., Pres. Z.S., V.P. Anthrop. Inst., &c., Chairman of the Department

It is impossible for us to commence the work of this section of the Association without having vividly brought to our minds the loss which has befallen us since our last meeting—the loss of one who was our most characteristic representative of the complex science of anthropology—one who had for many years conducted with extraordinary energy, amidst multifarious other avocations, a series of researches into the history, customs, and physical characters of the early inhabitants of our island, for which he was so especially fitted by his archæological, historical, and literary, as well as his anatomical knowledge, and who was also the most popular and brilliant expositor, to assemblies such as meet together on these occasions, of the results of those researches. I need scarcely say that I refer to Prof. Rolleston.

Within the last few months the study of our subject in this country has received an impulse from the publication of a book—small in size, it is true, but full of materials for thought and instruction—the "Anthropology" of Mr. E. B. Tylor, the first work published in English with that title, and one very different in its scope and method from the old ethnological treatises.

The immense array of facts brought together in a small compass, the terseness and elegance of the style, the good taste and feeling with which difficult and often burning questions are treated, should give this book a wide circulation among all classes, and thoroughly familiarise both the word and the subject to English readers.

The origin and early history of man's civilisation, his language, his arts of life, his religion, science, and social customs in the primitive conditions of society, are subjects in which, in consequence of their direct continuity with the arts and sciences, religious, political, and social customs among which we all live, by which we are all influenced, and about which we all have opinions, every person of ordinary education can and should take an interest. In fact, really to understand all these problems in the complex condition in which they are presented to us now, we ought to study them in their more simple forms, and trace them as far as may be to their origins.

But, as the author remarks, this book is only an introduction to anthropology, rather than a summary of all that it teaches; and some, even those that many consider the most important, branches of the subject are but lightly touched upon, or wholly passed over.

In one of the estimates of the character and opinions of the very remarkable man and eminent statesman, whose death the country was mourning last spring, it was stated: "Lord Beaconsfield had a deep-rooted conviction of the vast importance of race, as determining the relative dominance both of societies and of individuals" (*Spectator*, April 23, 1881); and with regard to the question of what he meant by "race," we have a key in the last published work of the same acute observer of mankind: "Language and religion do not make a race—there is only one thing which makes a race, and that is blood" ("Endymion," vol. ii. p. 205). Now "blood" used in this sense is defined as "kindred; relation by natural descent from a common ancestor; consanguinity" (Webster's "Dictionary"). The study of the true relationship of the different races of men is then not only interesting from a scientific point of view, but of great importance to statesmanship in such a country as this, embracing subjects representing almost every known modification of the human species, whose varied and often conflicting interests have to be regulated and provided for. It is to want of appreciation of its importance that many of the inconsistencies and shortcomings of the government of our dependencies and colonies are due, especially the great inconsistency between a favourite English theory and a too common English practice—the former being that all men are morally and intellectually alike, the latter being that all are equally inferior to himself in all respects: both propositions egregiously fallacious. The study of race is at a low ebb indeed when we hear the same contemptuous epithet of "nigger" applied indiscriminately by the Englishman abroad to the blacks of the West Coast of Africa, the Kaffirs of Natal, the Lascars of Bombay, the Hindoos of Calcutta, the aborigines of Australia, and even the Maoris of New Zealand!

But how is he to know better? Where in this country is any instruction to be had? Where are the books to which he may turn for trustworthy information? The subject, as I have said, is but slightly touched upon in the last published treatise on anthropology in our language. The great work of Pritchard, a compendium of all that was known at the time it was written, is now almost entirely out of date. In not a single university or public institution throughout the three kingdoms is there any kind of systematic teaching, either of physical or of any other branch of anthropology, except so far as comparative philology may be considered as bearing upon the subject. The one society of which it is the special business to promote the study of these questions, the Anthropological Institute of Great Britain and Ireland, is, I regret to say, far from flourishing. An anthropological museum, in the proper sense of the word, either public or private, does not exist in this country.

What a contrast is this to what we see in almost every other nation in Europe! At Paris there is, first, the Muséum d'Histoire Naturelle, where man, as a zoological subject—almost entirely neglected in our British Museum—has a magnificent gallery allotted to him, abounding not only in illustrations of osteology, but also in models, casts, drawings, and anatomical preparations showing various points in his physical or natural history, which is expounded to the public in the free lectures of the venerable Prof. Quatrefages and his able coadjutor, Dr. Hamy; there is also the vigorous Society of Anthropology, which is stated in the last annual report to number 720 members, showing an increase of forty-four during the year 1880, and which is forming a museum on a most extensive scale; and, finally, the School of Anthropology, founded by the illustrious Broca, whose untimely death last year, instead of paralysing, seems to have stimulated, the energies of colleagues and pupils into increased activity. In this school, supported partly by private subscriptions, partly by the public liberality of the Municipality of Paris, and of the Department of the Seine, are laboratories in which all the processes of anthropological manipulation are practised by students and taught to travellers. Here all the bodies of persons of outlandish nationalities dying in any of the hospitals of Paris are dissected by competent and zealous observers, who carefully record every peculiarity of structure discovered, and are thus laying the foundation for an exhaustive and trustworthy collection of materials for the comparative anatomy of the races of man. Here, furthermore, are lectureships on all the different branches. Biological and anatomical anthropology, ethnology, prehistoric, linguistic, social, and medical anthropology are all treated of separately by eminent professors who have made these departments their special study. The influence of so much activity is spreading beyond the capital. The foundation of an anthropological society at Lyons has been announced within the present year.

In Germany, although there is not at present any institution organised like the school at Paris, the flourishing state of the Berlin Ethnological Society, which also reports a large increase in the number of its members, the various other societies and journals, and the important contributions which are continually being made from the numerous intellectual centres of that land of learning, all attest the interest which the study of man excites there. In Italy, in the Scandinavian kingdoms, in Russia, and even in Spain, there are signs of similar activity. A glance at the recent periodical literature of America, especially the publications of the Smithsonian Institution, will show how strongly

the scientific work of that country is setting in the same direction.

It is true that a very great proportion of the energies of the societies, institutions, and individuals who cultivate this vast subject are, in all these lands, as it is indeed to so great an extent in our own, devoted to that branch which borders upon the old and favourite studies of archæology and geology. The fascinating power of the pursuit of the earliest traces of man's existence upon the earth, with the possibilities of obtaining some glimpses of his mode of origin, is attested in the devotion seen everywhere in museums, in separate publications, and in journals, to pre-historic anthropology.

But, though the study of man's origin and earliest appearances upon the earth, and that of the structural modifications to which in course of time he has arrived, or the study of races, are intimately related, and will ultimately throw light upon one another, I venture to think that the latter is the more pressing of the two, as it is certainly the more practically important; and hence the necessity for greater attention to physical anthropology. In seeking for a criterion upon which to base our study of races, in looking for essential proofs of consanguinity of descent from common ancestors in different groups of men, I have no hesitation in saying that we must first look to their physical or anatomical characters, next to their moral and intellectual characters—for our purpose more difficult of apprehension and comparison—and, lastly, as affording hints, often valuable in aid of our researches, but rarely to be depended upon, unless corroborated from other sources, to language, religion, and social customs.

The study of the physical or anatomical character of the races of man is unfortunately a subject beset with innumerable difficulties. It can only be approached with full advantage by one already acquainted with the ordinary facts of human anatomy, and with a certain amount of zoological training. The methods used by the zoologist in discriminating species and varieties of animals, and the practice acquired in detecting minute resemblances and differences that an ordinary observer might overlook, are just what are required in the physical anthropologist.

As the great problem which is at the root of all zoology is to discover a natural classification of animals, so the aim of zoological anthropology is to discover a natural classification of man. A natural classification is an expression of our knowledge of real relationship, of consanguinity—of "blood," as the author of "Endymion" expresses it. When we can satisfactorily prove that any two of the known groups of mankind are descended from the same common stock, a point is gained. The more such points we have acquired, the more nearly shall we be able to picture to ourselves, not only the present, but the past distribution of the races of man upon the earth, and the mode and order in which they have been derived from one another.

The difficulties in the way of applying zoological principles to the classification of man are vastly greater than in the case of most animals; the problem being, as we shall see, one of much greater complexity. When groups of animals become so far differentiated from each other as to represent separate species, they remain isolated; they may break up into further subdivisions—in fact, it is only by further subdivision that new species can be formed; but it is of the very essence of species, as now universally understood by naturalists, that they cannot recombine, and so give rise to new forms. With the varieties of man it is otherwise. They have never so far separated as to answer to the physiological definition of species. All races are fertile one with another, though perhaps in different degrees. Hence new varieties have constantly been formed, not only by the segmentation, as it were, of a portion of one of the old stocks, but also by various combinations of those already established.

Neither of the old conceptions of the history of man, which pervaded the thought, and form the foundation of the works of all ethnological writers up to the last few years, rest on any solid basis, nor account for the phenomena of the present condition and distribution of the species.

The one view—that of the monogenist—was that all races, as we see them now, are the descendants of a single pair, who, in a comparatively short period of time, spread over the world from one common centre of origin, and became modified by degrees in consequence of changes of climate and other external conditions. The other—that of the polygenist—is that a certain number of varieties or species (no agreement has been arrived at as to the number, which is estimated by different authorities at from three to twenty or more) have been independently created in different parts of the world, and have perpetuated the distinctive characters as well as the geographical position with which they were originally endowed.

The view which appears best to accord with what is now known of the characters and distribution of the races of man, and with the general phenomena of nature, may be described as a modification of the former of these hypotheses.

Without entering into the difficult question of the method of man's first appearance upon the world, we must assume for it a vast antiquity—at all events as measured by any historical standard. Of this there is now ample proof. During the long time he existed in the savage state—a time compared to which the dawn of our historical period was as yesterday—he was influenced by the operation of those natural laws which have produced the variations seen in other regions of organic nature. The first men may very probably have been all alike; but, when spread over the face of the earth, and become subject to all kinds of diverse external conditions—climate, food, competition with members of his own species or with wild animals—racial differences began slowly to be developed through the potency of various kinds of selection acting upon the slight variations which appeared in individuals in obedience to the tendency implanted in all living things.

Geographical position must have been one of the main elements in determining the formation and the permanence of races. Groups of men isolated from their fellows for long periods, such as those living on small islands, to which their ancestors may have been accidentally drifted, would naturally, in course of time, develop a new type of features, of skull, of complexion or hair. A slight set in one direction, in any of these characters, would constantly tend to intensify itself, and so new races would be formed. In the same way different intellectual or moral qualities would be gradually developed and transmitted in different groups of men. The longer a race thus formed remained isolated, the more strongly impressed and the more permanent would its characteristics become, and less liable to be changed or lost, when the surrounding circumstances were altered, or under a moderate amount of intermixture from other races—the more "true," in fact, would it be. On the other hand, on large continental tracts, where no "mountains interposed make enemies of nations," or other natural barriers form obstacles to free intercourse between tribe and tribe, there would always be a tendency towards uniformity, from the amalgamation of races brought into close relation by war or by commerce. Smaller or feebler races have been destroyed or absorbed by others impelled by superabundant population or other causes to spread beyond their original limits; or sometimes the conquering race has itself disappeared by absorption into the conquered.

Thus, for untold ages, the history of man has presented a shifting kaleidoscopic scene; new races gradually becoming differentiated out of the old elements, and, after dwelling a while upon the earth, either becoming suddenly annihilated or gradually merged into new combinations; a constant destruction and reconstruction; a constant tendency to separation and differentiation, and a tendency to combine again into a common uniformity—the two tendencies acting against and modifying each other. The history of these processes in former times, except in so far as they may be inferred from the present state of things, is a difficult study, owing to the scarcity of evidence. If we had any approach to a complete palæontological record, the history of man could be reconstructed: but nothing of the kind is forthcoming. Evidences of the anatomical characters of man as he lived on the earth during the time when the great racial characteristics were being developed, during the long ante-historic period in which the negro, the Mongolian, and the Caucasian were being gradually fashioned into their respective types, is entirely wanting, or, if any exists, it is at present safely buried in the earth, perhaps to be revealed at some unexpected time and in some unforeseen manner.

It will be observed, and perhaps observed with perplexity by some, that no definition has as yet been given of the oft-recurring word "race." The sketch just drawn of the past history of man must be sufficient to show that any theory implying that the different individuals composing the human species can be parcelled out into certain definite groups, each with its well-marked and permanent limits separating it from all others, has no scientific foundation; but that in reality these individuals are aggregated into a number of groups of very different value in a zoological sense, with characters more or less strongly marked

and permanent, and often passing insensibly into one another. The great groups are split up into minor subdivisions, and filling up the gaps between them all are intermediate or intercalary forms, derived either from the survival of individuals retaining the generalised or ancestral characters of a race from which two branches have separated and taken opposite lines of modification, or from the reunion of members of such branches in recent times. If we could follow those authors who can classify mankind into such divisions as trunks, branches, races, and sub-races, each having its definite and equivalent meaning, our work would appear to be greatly simplified, although perhaps we should not be so near the truth we are seeking. But being not yet in a position to define what amount of modification is necessary to constitute distinction of race, I am compelled to use the word vaguely for any considerable group of men who resemble each other in certain common characters transmitted from generation to generation.

In approaching the question of the classification of the races of man from a physical point of view, we must bestow great care upon the characters upon which we rely in distinguishing one group from another. It is well known in zoology that the modifications of a single organ or system may be of great value, or may be quite useless according as such modifications are correlated with others in different organs or systems, or are mere isolated examples of variation in the economy of the animal without structural changes elsewhere. The older ornithologists associated in one order all the birds with webbed feet, and the order thus constituted, *Natatores* or *Palmipedes*, which received the great sanction of Cuvier, still stands in many zoological compilations. Recent investigations into the anatomy of birds have shown that the species thus associated together show no other sign of natural affinity, and no evidence of being derived from the same stock. In fact, there is tolerably good proof that the webbing of the feet is a merely adaptive character, developed or lost, present or absent, irrespective of other structural modifications. In the same way, when anthropology was less advanced than it is now, it was thought that the distinction between long and short-headed, dolichocephalic and brachycephalic, people, pointed out by Retzius, indicated a primary division of the human species; but it was afterwards discovered that, although the character was useful otherwise, it was one of only secondary importance, as the long-headed as well as the short-headed group both included races otherwise of the strongest dissimilarity.

In all classifications the point to be first ascertained is the fundamental plan of construction; but in cases where the fundamental plan has undergone but little modification, we are obliged to make use of what appear trivial characters, and compensate for their triviality by their number. The more numerous the combinations of specialised characters, by which any species or race differs from its congeners, the more confidence we have in their importance. The separation of what is essential from what is incidental or merely superficial in such characters lies at the root of all the problems of this nature that zoologists are called upon to solve; and in proportion as the difficulties involved in this delicate and often perplexing discrimination are successfully met and overcome will the value of the conclusions be increased. These difficulties, so familiar in zoology, are still greater in the case of anthropology. The differences we have to deal with are often very slight; their significance is at present very little understood. We go on expending time and trouble in heaping up elaborate tables of measurements, and minutely recording every point that is capable of description, with little regard to any conclusions that may be drawn from them. It is certainly time now to endeavour, if possible, to discriminate characters which indicate deep-lying affinity from those that are more transient, variable, or adaptive, and to adjust, as far as may be, the proper importance to be attached to each.

It is, however, quite to be expected that, in the infancy of all sciences, a vast amount of labour must be expended in learning the methods of investigation. In none has this been more conspicuous than in the subject under consideration. Many have come to despair, for instance, of any good commensurate with the time it occupies, coming of the minute and laborious work involved in craniometry. This is because nearly all our present methods are tentative. We have not yet learnt, or are only beginning to learn, what lines of investigation are profitable and what are barren. The results, even as far as we have gone, are, however, quite sufficient, in my opinion, to justify perseverance. I am, however, not so sure whether it be yet time to answer the demand, so eager and so natural, which is being made in many quarters, for the formulation of a definite plan of examination, measurement, and description to which all future investigation should rigidly adhere. All steps to promote agreement upon fundamental points are to be cordially welcomed, and meetings or congresses convened for such a purpose will be of use by giving opportunities for the impartial discussion of the relative value of different methods; but the agreement will finally be brought about by the general adoption of those measurements and methods which experience proves to be the most useful, while others will gradually fall into disuse by a kind of process of natural selection.

The changes and improvements which are being made yearly, almost monthly, in instruments and in methods, show what we should lose if we were to stop at any given period, and decree in solemn conclave that this shall be our final system, this instrument and this method shall be the only one used throughout the world, that no one shall depart from it. We scarcely need to ask how long such an agreement would be binding. The subject is not sufficiently advanced to be reduced to a state of stagnation such as this would bring it to.

To take an example from what is perhaps the most important of the anatomical characters by which man is distinguished from the lower animals, the superior from the inferior races of man; the smaller or greater projection forwards of the lower part of the face in relation to the skull proper, or that which contains the brain. From the time when Camper drew his facial angle, to the present day, the readiest and truest method of estimating this projection has occupied the attention of anatomists and anthropologists, and we are still far from any general agreement. Every country, every school, has its own system, so different that comparison with one another is well nigh impossible. This is undoubtedly an evil; but the question is whether we should all agree to adopt one of the confessedly defective systems now in vogue, or whether we should not rather continue to hope for, and endeavour to find, one which may not be subject to the well-known objections urged against all.

We want, especially in this country, more workers, trained and experienced men who will take up the subject seriously, and devote themselves to it continuously. Of such we may say, without offence to those few who have done occasional excellent work in physical anthropology, but whose chief scientific activity lies in other fields, we have not one. In the last number of the French *Revue d'Anthropologie*, a reference caught my eye to a craniometrical method in use by the "English school" of anthropologists. It was a reference only to a method which I had ventured to suggest, but which, as far as I know, has not been adopted by any one else. A school is just what we have not, and what we want—a body of men not only willing to learn, but able to discuss, to criticise, to give their approval to, or reduce to its proper level, the results put forth by our few original investigators and writers. The rapidity with which any one of the most slender pretensions who ventures into the field (I speak from painful experience) is raised to be an oracle among his fellows is one of the most alarming proofs of the present barrenness of the land.

Another most urgent need is the collection and preservation of the evidences of the physical structure of the various modifications of man upon the earth. Especially urgent is this now, as we live in an age in which, in a far greater degree than any previous one, the destruction of races, both by annihilation and absorption, is going on. The world has never witnessed such changes in its ethnology as those now taking place, owing to the rapid extension of maritime discovery and maritime commerce, which is especially affecting the island population among which, more than elsewhere, the solution of the most important anthropological problems may be looked for. If we have at present neither the knowledge nor the leisure to examine and describe, we can at least preserve from destruction the materials for our successors to work upon. Photographs, models, anatomical specimens, skeletons or parts of skeletons, with their histories carefully registered, of any of the so-called aboriginal races, now rapidly undergoing extermination or degeneration, will be hereafter of inestimable value. Drawings, descriptions, and measurements are also useful, though in a far less degree, as allowance must always be made for imperfections in the methods as well as the capacity of the artist or observer. Such collections must be made upon a far larger scale than has hitherto been attempted, as, owing to the difficulties already pointed out in the classification of man, it is only by large numbers that the errors arising

from individual peculiarities or accidental admixture can be obviated, and the prevailing characteristics of a race or group truly ascertained. It is only in an institution commanding the resources of the nation that such a collection can be formed, and it may therefore be confidently hoped that the trustees of the British Museum will appropriate some portion of the magnificent new building, which has been provided for the accommodation of their natural history collections, to this hitherto neglected branch of the subject.

I have mentioned two of the needs of anthropology in this country—more workers and better collections: there is still a third—that of a society or institution in which anthropologists can meet and discuss their respective views, with a journal in which the results of their investigations can be laid before the public, and a library in which they can find the books and periodicals necessary for their study. All this ought to be provided by the Anthropological Institute of Great Britain and Ireland, which originated in the amalgamation of the old Ethnological and Anthropological Societies. But, as I intimated some time ago, the Institute does not at the present time flourish as it should; its meetings are not so well attended as they might be; the journal is restricted in its powers of illustration and printing by want of funds; the library is quite insufficient for the needs of the student.

This certainly does not arise from any want of good management in the Society itself. Its afairs have been presided over and administered by some of the most eminent and able men the country has produced. Huxley, Lubbock, Busk, Evans, Tylor, and Pitt-Rivers have in succession given their energies to its service, and yet the number of its members is falling away, its usefulness is crippled, and its very existence seems precarious. Some decline to join the Institute, others leave it upon the plea that, being unable from distance or other causes to attend the meetings, they cannot obtain the full return for their subscriptions; others on the ground that the journal does not contain the exact information which they require.

There surely is to be found a sufficient number of persons who are influenced by different considerations, who feel that anthropological science is worth cultivating, and that those who are laboriously and patiently tracing out the complex problems of man's diversity and man's early history are doing a good work, and ought to be encouraged by having the means afforded them of carrying on their investigations and of placing the results of their researches before the world—who feel, moreover, that there ought to be some central body, representing the subject, which may, on occasion, influence opinion or speak authoritatively on matters often of great practical importance to the nation.

There must be many in this great and wealthy country who feel that they are helping a good cause in joining such a society, even if they are not individually receiving what they consider a full equivalent for their small subscription—many who feel satisfaction in helping the cause of knowledge, in helping to remove the opprobrium that the British Anthropological Society alone of those of the world is lacking in vitality, and in helping to prevent this country from falling behind all the nations in the cultivation of a science in which, for the strongest reasons, it might be expected to hold the foremost place. It is a far more grateful task to maintain, extend, and if need be improve, an existing organisation, than to construct a new one. I feel, therefore, no hesitation in urging upon all who take interest in the promotion of the study of anthropology to rally round the Institute, and to support the endeavours of the present excellent president to increase its usefulness.

Department of Anatomy and Physiology

OPENING ADDRESS BY J. BURDON-SANDERSON, M.D., LL.D., F.R.S., PROFESSOR OF PHYSIOLOGY IN UNIVERSITY COLLEGE, LONDON, VICE-PRESIDENT OF THE SECTION

On the Discoveries of the Past Half-Century relating to Animal Motion

THE two great branches of Biology with which we concern ourselves in this section, Animal Morphology and Physiology, are most intimately related to each other. This arises from their having one subject of study—the living animal organism. The difference between them lies in this, that whereas the studies of the anatomist lead him to fix his attention on the organism itself, to us physiologists it, and the organs of which it is made up, serve only as *vestigia*, by means of which we investigate the vital processes of which they are alike the causes and consequences.

To illustrate this I will first ask you to imagine for a moment that you have before you one of those melancholy remainders of what was once an animal—to wit, a rabbit—which one sees exposed in the shops of poulterers. We have no hesitation in recognising that remainder as being in a certain sense a rabbit; but it is a very miserable vestige of what was a few days ago enjoying life in some wood or warren, or more likely on the sand-hills near Ostend. We may call it a rabbit if we like, but it is only a remainder—not the thing itself.

The anatomical preparation which I have in imagination placed before you, although it has lost its inside and its outside, its integument and its viscera, still retains the parts for which the rest existed. The final cause of an animal, whether human or other, is muscular action, because it is by means of its muscles that it maintains its external relations. It is by our muscles exclusively that we act on each other. The articulate sounds by which I am addressing you are but the results of complicated combinations of muscular contractions—and so are the scarcely appreciable changes in your countenances by which I am able to judge how much, or how little, what I am saying interests you.

Consequently the main problems of physiology relate to muscular action, or, as I have called it, animal motion. They may be divided into two—namely (1) in what does muscular action consist—that is, what is the process of which it is the effect or outcome? and (2) how are the motions of our bodies co-ordinated or regulated? It is unnecessary to occupy time in showing that, excluding those higher intellectual processes which, as they leave no traceable marks behind them, are beyond the reach of our methods of investigation, these two questions comprise all others concerning animal motion. I will therefore proceed at once to the first of them—that of the process of muscular contraction.

The years which immediately followed the origin of the British Association exceeded any earlier period of equal length in the number and importance of the new facts in morphology and in physiology which were brought to light; for it was during that period that Johannes Müller, Schwann, Henle, and, in this country, Sharpey, Bowman, and Marshall Hall, accomplished their productive labours. But it was introductory to a much greater epoch. It would give you a true idea of the nature of the great advance which took place about the middle of this century if I were to define it as the epoch of the death of "vitalism." Before that time, even the greatest biologist—*e.g.* J. Müller—recognised that the knowledge they possessed both of vital and physical phenomena was insufficient to refer both to a common measure. The method, therefore, was to study the processes of life in relation to each other only. Since that time it has become fundamental in our science not to regard any vital process as understood at all, unless it can be brought into relation with physical standards, and the methods of physiology have been based exclusively on this principle. Let us inquire for a moment what causes have conduced to the change.

The most efficient cause was the progress which had been made in physics and chemistry, and particularly those investigations which led to the establishment of the doctrine of the Conservation of Energy. In the application of this great principle to physiology, the men to whom we are indebted are, first and foremost, J. R. Mayer, of whom I shall say more immediately; and secondly, to the great physiologists still living and working among us, who were the pupils of J. Müller—viz. Helmholtz, Ludwig, Du Bois-Reymond, and Brücke.

As regards the subject which is first to occupy our attention, that of the *process* of muscular contraction, J. R. Mayer occupies so leading a position that a large proportion of the researches which have been done since the new era, which he had so important a share in establishing, may be rightly considered as the working out of principles enunciated in his treatise[1] on the relation between organic motion and exchange of material. The most important of these were, as expressed in his own words: (1) "That the chemical force contained in the ingested food and in the inhaled oxygen is the source of the motion and heat which are the two products of animal life; and (2) that these products vary in amount with the chemical process which produces them." Whatever may be the claims of Mayer to be regarded as a great discover in physics, there can be no doubt

[1] J. R. Mayer, "Die organische Bewegung in ihrem Zusammenhange mit dem Stoffwechsel: ein Beitrag zur Naturkunde," Heilbronn, 1845.

that as a physiologist he deserves the highest place that we can give him, for at a time when the notion of the correlation of different modes of motion was as yet very unfamiliar to the physicist, he boldly applied it to the phenomena of animal life, and thus re-united physiology with natural philosophy, from which it had been rightly, because unavoidably, severed by the vitalists of an earlier period.

Let me first endeavour shortly to explain how Mayer himself applied the principle just enunciated, and then how it has been developed experimentally since his time.

The fundamental notion is this: the animal body resembles, as regards the work it does and the heat it produces, a steam-engine, in which fuel is continually being used on the one hand, and work is being done and heat produced on the other. The using of fuel is the chemical process, which in the animal body, as in the steam-engine, is a process of oxidation. Heat and work are the useful products, for as, in the higher animals, the body can only work at a constant temperature of about 100° F., heat may be so regarded.

Having previously determined the heat and work severally producible by the combustion of a given weight of carbon, from his own experiments and from those of earlier physicists, Mayer calculated that if the oxidation of carbon is assumed to represent approximately the oxidation process of the body, the quantity of carbon actually burnt in a day is far more than sufficient to account for the day's work, and that of the material expended in the body not more than one-fifth was used in the doing of work, the remaining four-fifths being partly used, partly wasted in heat production.

Having thus shown that the principles of the correlation of process and product hold good, so far as its truth could then be tested, as regards the whole organism, Mayer proceeded to inquire into its applicability to the particular organ whose function it is "to transform chemical difference into mechanical effect"—namely, muscle. Although, he said, a muscle acts under the direction of the will, it does not derive its power of acting from the will any more than a steamboat derives its power of motion from the helmsman. Again (and this was of more importance, as being more directly opposed to the prevalent vitalism), a muscle, like the steamboats use in the doing of work, not the material of its own structure, or mechanism, but the fuel—*i.e.* the nutriment—which it derives directly from the blood which flows through its capillaries. "The muscle is the instrument by which the transformation of force is accomplished, not the material which is itself transformed." This principle he exemplified in several ways, showing that if the muscle of our bodies worked, as was formerly supposed, at the expense of their own substance, their whole material would be used up in a few weeks, and that in the case of the heart, a muscle which works at a much greater rate than any other, it would be expended in as many days—a result which necessarily involved the absurd hypothesis that the muscular fibres of our hearts are so frequently disintegrated and reintegrated that we get new hearts once a week.

On such considerations Mayer founded the prevision, that, as soon as experimental methods should become sufficiently perfect to render it possible to determine with precision the limits of the chemical process either in the whole animal body or in a single muscle during a given period, and to measure the production of heat and the work done during the same period, the result would show a quantitative correlation between them.

If the time at our disposal permitted, I should like to give a short account of the succession of laborious investigations by which these previsions have been verified. Begun by Bidder and Schmidt in 1851,[1] continued by Pettenkofer and Voit,[2] and by the agricultural physiologists[3] with reference to herbivora, they are not yet by any means completed. I must content myself with saying that by these experiments the first and second parts of this great subject—namely, the limits of the chemical process of animal life and its relation to animal motion under different conditions—have been satisfactorily worked out, but that the quantitative relations of heat-production are as yet only insufficiently determined.

Let me sum up in as few words as possible how far what we have now learnt by experiment justifies Mayer's anticipations, and how it falls short of or exceeds them. First of all, we are as certain as of any physical fact that the animal body in doing work does not use its own material—that, as Mayer says, the oil to his lamp of life is food; but in addition to this we know what he was unaware of, that what is used is not only not the living protoplasm itself, but is a kind of material which widely differs from it in chemical properties. In what may be called commercial physiology—*i.e.*, in the literature of trade puffs—one still meets with the assumption that the material basis of muscular motion is nitrogenous; but by many methods of proof it has been shown that the true "Oel in der Flamme des Lebens" is not proteid substance, but sugar, or sugar-producing material. The discovery of this fundamental truth we owe first to Bernard (1850-56), who brought to light the fact that such material plays an important part in the nutrition of every living tissue; secondly, to Voit (1866), who in elaborate experiments on carnivorous animals, during periods of rest and exertion, showed that, in comparing those conditions, no relation whatever shows itself between the quantity of proteid material (flesh) consumed, and the amount of work done; and finally to Frankland, Fick, and his associate Wislicenus, as to the work-yielding value of different constituents of food, and as to the actual expenditure of material in man during severe exertion. The subjects of experiment used by the two last-mentioned physiologists were themselves; the work done was the mountain ascent from Interlaken to the summit of the Faulhorn; the result was to prove that the quantity of material used was proportional to the work done, and that that material was such as to yield water and carbonic acid exclusively.

The investigators to whom I have just referred aimed at proving the correlation of process and product for the whole animal organism. The other mode of inquiry proposed by Mayer, the verification of his principle in respect of the work-doing mechanism—that is to say, in respect of muscle taken separately—has been pursued with equal perseverance during the last twenty years, and with greater success; for in experimenting on a separate organ, which has no other functions excepting those which are in question, it is possible to eliminate uncertainties which are unavoidable when the conditions of the problem are more complicated. Before I attempt to sketch the results of these experiments, I must ask your attention for a moment to the discoveries made since Mayer's epoch, concerning a closely related subject, that of the Process of Respiration.

I wish that I had time to go back to the great discovery of Priestley (1776), that the essential facts in the process of respiration are the giving off of fixed air, as he called it, and the taking in of dephlogisticated air, and to relate to you the beautiful experiments by which he proved it; and then to pass on to Lavoisier (1777), who, on the other side of the Channel, made independently what was substantially the same discovery a little after Priestley, and added others of even greater moment. According to Lavoisier, the chemical process of respiration is a slow combustion which has its seat in the lungs. At the time that Mayer wrote, this doctrine still maintained its ascendency, although the investigations of Magnus (1838) had already proved its fallacy. Mayer himself knew that the blood possessed the property of conveying oxygen from the lungs to the capillaries, and of conveying carbonic acid gas from the capillaries to the lungs, which was sufficient to exclude the doctrine of Lavoisier. Our present knowledge of the subject was attained by two methods—viz., first, the investigation of the properties of the colouring matter of the blood, since called "hæmoglobin," the initial step in which was made by Prof. Stokes in 1862; and secondly, the application of the mercurial air-pump as a means of determining the relations of oxygen and carbonic acid gas to the living blood and tissues. The last is a matter of such importance in relation to our subject that I shall ask your special attention to it. Suppose that I have a barometer of which the tube, instead of being of the ordinary form, is expanded at the top into a large bulb of one or two litres capacity, and that, by means of some suitable contrivance, I am able to introduce, in such a way as to lose no time and to preclude the possibility of contact with air, a fluid ounce of blood from the artery of a living animal into the vacuous space—what would happen? Instantly the quantity of blood would be converted into froth, which would occupy the whole of the large bulb. The colour of the froth would at first be scarlet, but would speedily change to crimson. It would soon subside, and we should then have the cavity which was before vacuous occupied by the blood and its gases—namely, the oxygen, carbonic acid gas, and nitrogen previously contained in it. And if we had the means (which

[1] Bidder and Schmidt, "Die Verdauungssäfte und der Stoffwechsel," Leipzig, 1852.

[2] Pettenkofer and Voit, *Zeitschr. f. Biologie*, passim, 1866-80.

[3] Henneberg and Stohmann, "Beiträge zur Begründung einer rationellen Futterung der Wiederkäuer," Brunswick and Göttingen, 1860-70.

actually exist in the gas-pump) of separating the gaseous mixture from the liquid, and of renewing the vacuum, we should be able to determine (1) the total quantity of gases which the blood yields, and (2), by analysis, the proportion of each gas.

Now, with reference to the blood, by the application of the "blood-pump," as it is called, we have learnt a great many facts relating to the nature of respiration, particularly that the difference of venous from arterial blood depends not on the presence of "effete matter," as used to be thought, but on the less amount of oxygen held by its colouring matter, and that the blood which flows back to the heart from different organs, and at different times, differs in the amount of oxygen and of carbonic acid gas it yields, according to the activity of the chemical processes which have their seat in the living tissues from which it flows.[1] But this is not all that the blood-pump has done for us. By applying it not merely to the blood, but to the tissues, we have learnt that the doctrine of Lavoisier was wrong, not merely as regards the place, but as regards the nature of the essential process in respiration. The fundamental fact which is thus brought to light is this, that although living tissues are constantly and freely supplied with oxygen, and are in fact constantly tearing it from the hæmoglobin which holds it, yet they themselves yield no oxygen to the vacuum. In other words, the oxygen which living protoplasm seizes upon with such energy that the blood which flows by it is compelled to yield it up, becomes so entirely part of the living material itself that it cannot be separated even by the vacuum. It is in this way only that we can understand the seeming paradox that the oxygen, which is conveyed in abundance to every recess of our bodies by the blood-stream, is nowhere to be found. Notwithstanding that no oxidation-product is formed, it becomes latent in every bit of living protoplasm; stored up in quantity proportional to its potential activity—*i.e.* to the work, internal or external, it has to do.

Thus you see that the process of tissue respiration—in other words, the relation of living protoplasm to oxygen—is very different from what Mayer, who localised oxidation in the capillaries, believed it to be. And this difference has a good deal to do with the relation of Process to Product in muscle. Let us now revert to the experiments on this subject which we are to take as exemplification of the truth of Mayer's forecasts.

The living muscle of a frog is placed in a closed chamber, which is vacuous—*i.e.* contains only aqueous vapour. The chamber is so arranged that the muscle can be made to contract as often as necessary. At the end of a certain period it is found that the chamber now contains carbonic acid gas in quantity corresponding to the number of contractions the muscle has performed. The water which it has also given off cannot of course be estimated. Where do these two products come from? The answer is plain. The muscle has been living all the time, for it has been doing work, and (as we shall see immediately) producing heat. What has it been living on? Evidently on stored material. If so, of what nature? If we look for the answer to the muscle, we shall find that it contains both proteid and sugar-producing material, but which is expended in contraction we are not informed. There is, however, a way out of the difficulty. We have seen that the only chemical products which are given off during contraction are carbonic acid gas and water. It is clear, therefore, that the material on which it feeds must be something which yields, when oxidised, these products, and these only. The materials which are stored in muscle are oxygen and sugar, or something resembling it in chemical composition.

And now we come to the last point I have to bring before you in connection with this part of my subject. I have assumed up to this moment that heat is always produced when a muscle does work. Most people will be ready to admit as evidence of this, the familiar fact that we warm ourselves by exertion. This is in reality no proof at all.

The proof is obtained when, a muscle being set to contract, it is observed that at each contraction it becomes warmer. In such an experiment, if the heat capacity of muscle is known, the weight of the particular muscle, and the increase of temperature, we have the quantity of heat produced.

If you determine these data in respect of a series of contractions, arranging the experiments so that the work done in each contraction is measured, and immediately thereupon reconverted into heat, the result gives you the total product of the oxidation process in heat.

[1] Ludwig's first important research on this subject was published in 1862.

If you repeat the same experiment in such a way that the work done in each contraction is not so reconverted, the result is *less* by the quantity of heat corresponding to the work done. The results of these two experiments have been found by Prof. Fick to cover each other very exactly. I have stated them in a table[1] in which we have the realisation as regards a single muscle of the following forecast of Mayer's as regards the whole animal organism. "Convert into heat," he said, "by friction or otherwise, the mechanical product yielded by an animal in a given time, add thereto the heat produced in the body directly during the same period, and you will have the total quantity of heat which corresponds to the chemical processes." We have seen that this is realisable as regards muscle, but it is not even yet within reach of experimental verification as regards the whole animal.

I now proceed abruptly (for the time at our disposal does not admit of our spending it on transitions) to the consideration of the other great question concerning vital motion, namely the question how the actions of the muscles of an animal are so regulated and co ordinated as to determine the combined movements, whether rhythmical or voluntary, of the whole body.

As every one knows who has read the "Lay Sermons," the nature and meaning of these often unintentional but always adapted motions, which constitute so large a part of our bodily activity, was understood by Descartes early in the seventeenth century. Without saying anything as to his direct influence on his contemporaries and successors, there can be no doubt that the appearance of Descartes was coincident with a great epoch—an epoch of great men and great achievements in the acquirement of man's intellectual mastery over nature. When he interpreted the unconscious closing of the eyelids on the approach of external objects, the acts of coughing, sneezing, and the like as mechanical and reflected processes, he neither knew in what part of the nervous system the mechanisms concerned were situated, nor how they acted.[2] It was not until a hundred years after that Whytt and Hales made the fundamental experiments on beheaded frogs, by which they showed that the involuntary motions which such preparations execute cease when the whole of the spinal cord is destroyed—that if the back part of the cord is destroyed, the motions of the hind limbs, if the fore part, those of the fore limbs cease. It was in 1751 that Dr. Whytt published in Edinburgh his work on the involuntary motions of animals. After this the next great step was made within the recollection of living physiologists: a period to which, as it coincided with the event which we are now commemorating—the origin of the British Association—I will now ask your special attention.

Exactly forty-nine years ago Dr. Marshall Hall communicated to the Zoological Society of London the first account of his experiments on the reflex function of the spinal cord. The facts which he had observed, and the conclusions he drew from them, were entirely new to him, and entirely new to the physiologists to whom his communication was addressed. Nor can there be any reason why the anticipation of his fundamental discovery by Dr. Whytt should be held to diminish his merit as an original

[2] Descartes' scheme of the central nervous mechanism comprised all the parts which we now regard as essential to "reflex-action." Sensory nerves were represented by threads (filets) which connected all parts of the body to the brain ("Œuvres," par V. Cousin, vol. iv. p. 359); motor nerves by tubes which extended from the brain to the muscles; "motor centres" by "pores" which were arranged on the internal surface of the ventricular cavity of the brain and guarded the entrances to the motor tubes. This cavity was supposed to be kept constantly charged with "animal spirits" furnished to it from the heart by arteries specially destined for the purpose. Any "incitation" of the surface of the body by an external object which affects the organs of sense does so, according to Descartes, by producing a *motion* at the incited part. This is communicated to the pore by the thread and causes it to open, the consequence of which is that the "animal spirit" contained in the ventricular cavity enters the tube and is conveyed by it to the various muscles with which it is connected, so as to produce the appropriate motions. The whole system, although it was placed under the supervision of the "*âme raisonable*" which had its office in the pineal gland, was capable of working independently. As instances of this mechanism Descartes gives the withdrawal of the foot on the approach of hot objects, the actions of swallowing, yawning, coughing, &c. As it is necessary that, in the performance of these complicated motions, the muscles concerned should contract in succession, provision is made for this in the construction of the systems of tubes which represent the motor nerves. The weakness of the scheme lies in the absence of fact basis. Neither threads nor pores nor tubes have any existence.

investigator. In the face of historical fact it is impossible to regard him as the discoverer of the "reflex function of the spinal cord," but we do not the less owe him gratitude for the application he made of the knowledge he had gained by experiments on animals to the study of disease. For no one who is acquainted with the development of the branch of practical medicine which relates to the diseases of the central nervous system will hesitate in attributing the rapid progress which has been made in the diagnosis and treatment of these diseases, to the impulse given by Dr. Marshall Hall to the study of nervous pathology.

In the mind of Dr. Marshall Hall the word reflex had a very restricted meaning. The term "excito-motary function," which he also used, stood in his mind for a group of phenomena of which it was the sole characteristic that a sensory impression produced a motor response. During the thirty years which have elapsed since his death, the development of meaning of the word reflex has been comparable to that of a plant from a seed. The original conception of reflex action has undergone, not only expansion, but also modification, so that in its wider sense it may be regarded as the empirical development of the philosophical views of the animal mechanism promulgated by Descartes. Not that the work of the past thirty years by which the physiology of the nervous system has been constituted can be attributed for a moment to the direct influence of Descartes. The real epoch-maker here was Johannes Müller. There can be no doubt that Descartes' physiological speculations were well known to him, and that his large acquaintance with the thought and work of his predecessors conduced, with his own powers of observation, to make him the great man that he was; but to imagine that his ideas of the mechanism of the nervous system were inspired, or the investigations by which, contemporaneously with Dr. Marshall Hall, he demonstrated the fundamental facts of reflex action, were suggested by the animal automatism of Descartes, seems to me wholly improbable.

I propose, by way of conclusion, to attempt to illustrate the nature of reflex action in the larger sense, or, as I should prefer to call it, the Automatic Action of Centres, by a single example —that of the nervous mechanism by which the circulation is regulated.

The same year that J. R. Mayer published his memorable essay, it was discovered by E. H. Weber that, in the vagus nerve, which springs from the medulla oblongata and proceeds therefrom to the heart, there exist channels of influence by which the medulla acts on that wonderful muscular mechanism. Almost at the same time with this, a series of discoveries [1] were made relating to the circulation, which, taken together, must be regarded as of equal importance with the original discovery of Harvey. First, it was found by Henle that the arterial blood-vessels by which blood is distributed to brain, nerve, muscle, gland, and other organs, are provided with muscular walls like those of the heart itself, by the contraction or dilatation of which the supply is increased or diminished according to the requirements of the particular organ. Secondly, it was discovered simultaneously, but independently, by Brown-Séquard and Augustus Waller, that these arteries are connected by nervous channels of influence with the brain and spinal cord, just as the heart is. Thirdly, it was demonstrated by Bernard that what may be called the heart-managing channels spring from a small spot of grey substance in the medulla oblongata, which we now call the "heart-centre"; and a little later by Schiff, that the artery-regulating channels spring from a similar head-central office, also situated in the medulla oblongata, but higher up, and from subordinate centres in the spinal cord.

If I had the whole day at my disposal and your patience were inexhaustible, I might attempt to give an outline of the issues to which these five discoveries have led. As it is, I must limit myself to a brief discussion of their relations to each other, in order that we may learn something from them as to the nature of automatic action.

Sir Isaac Newton, who, although he knew nothing about the structure of nerves, made some shrewd forecasts about their action, attributed to those which are connected with muscles an alternative function. He thought that by means of motor nerves the brain could determine either relaxation or contraction of muscles. Now as regards ordinary muscles, we know that this is not the case. We can will only the shortening of a muscle, not its lengthening. When Brown-Séquard discovered the function of the motor nerves of the blood-vessels, he assumed that the same limitation was applicable to it as to that of muscular nerves in general. It was soon found, however, that this assumption was not true in all cases—that there were certain instances in which, when the vascular nerves were interfered with, dilatation of the blood-vessels, consequent on relaxation of their muscles, took place; and that, in fact, the nervous mechanism by which the circulation is regulated is a highly-complicated one, of which the best that we can say is that it is perfectly adapted to its purpose. For while every organ is supplied with muscular arteries, and every artery with vascular nerves, the influence which these transmit is here relaxing, there constricting, according (1) to the function which the organ is called upon to discharge; and (2) the degree of its activity at the time. At the same time the whole mechanism is controlled by one and the same central office, the locality of which we can determine with exactitude by experiment on the living animal, notwithstanding that its structure affords no indication whatever of its fitness for the function it is destined to fulfil. To judge of the complicated nature of this function we need only consider that in no single organ of the body is the supply of blood required always the same. The brain is during one hour hard at work, during the next hour asleep; the muscles are at one moment in severe exercise, the next in complete repose; the liver, which before a meal is inactive, during the process of digestion is turgid with blood, and busily engaged in the chemical work which belongs to it. For all these vicissitudes the tract of grey substance which we call the *vascular centre* has to provide. Like a skilful steward of the animal household, it has, so to speak, to exercise perfect and unfailing foresight, in order that the nutritive material which serves as the oil of life for the maintenance of each vital process, may not be wanting. The fact that this wonderful function is localised in a particular bit of grey substance is what is meant by the expression "automatic action of a centre."

But up to this point we have looked at the subject from one side only.

No state ever existed of which the administration was exclusively executive—no government which was, if I may be excused the expression, absolutely absolute. If in the animal organism we impose on a centre the responsibility of governing a particular mechanism or process, independently of direction from above, we must give that centre the means of being itself influenced by what is going on in all parts of its area of government. In other words, it is as essential that there should be channels of information passing inwards, as that there should be channels of influence passing outwards. Now what is the nature of these channels of information? Experiment has taught us not merely with reference to the regulation of the circulation, but with reference to all other automatic mechanisms, that they are as various in their adaptation as the outgoing channels of influence. Thus the vascular centre in the medulla oblongata is so cognisant of the chemical condition of the blood which flows through it, that if too much carbonic acid gas is contained in it, the centre acts on information of the fact, so as to increase the velocity of the blood-stream, and so promote the arterialisation of the blood. Still more strikingly is this adaptation seen in the arrangement by which the balance of pressure and resistance in the blood-vessels is regulated. The heart, that wonderful muscular machine by which the circulation is maintained, is connected with the centre, as if by two telegraph wires—one of which is a channel of influence, the other of information. By the latter the engineer who has charge of that machine sends information to headquarters whenever the strain on his machine is excessive, the certain response to which is relaxation of the arteries and diminution of pressure. By the former he is enabled to adapt its rate of working to the work it has to do.

If Dr. Whytt, instead of cutting off the head of his frog, had removed only its brain—*i.e.*, the organ of thought and consciousness—he would have been more astonished than he actually was at the result; for a frog so conditioned exhibits, as regards its bodily movements, as perfect adaptiveness as a normal frog. But very little careful observation is sufficient to show the difference. Being incapable of the simplest mental acts, this true animal automaton has no notion of requiring food or of seeking it, has no motive for moving from the place it happens to

[1] The dates of the discoveries relating to this subject here referred to are as follows:—Muscular Structure of Arteries, Henle, 1841; Function of Cardiac Vagus, E. H. Weber, 1845; Constricting Nerves of Arteries, B. Séquard, 1852, Aug. Waller, 1853; Cardiac Centre, Bernard, 1858; Vascular Centre, Schiff, 1858; Dilating Nerves, Schiff, 1854; Eckhard, 1864; Lovén, 1866. Of the more recent researches by which the further elucidation of the mechanism by which the distribution of blood is adapted to the requirements of each organ, the most important are those of Ludwig and his pupils and of Heidenhain.

occupy, emits no utterance of pleasure or distress. Its life processes continue so long as material remains, and are regulated mechanically.

To understand this all that is necessary is to extend the considerations which have been suggested to us in our very cursory study of the nervous mechanism by which the working of the heart and of arteries is governed, to those of locomotion and voice. Both of these we know, on experimental evidence similar to that which enables us to localise the vascular centre, to be regulated by a centre of the same kind. If the behaviour of the brainless frog is so natural that even the careful and intelligent observer finds it difficult to attribute it to anything less than intelligence, let us ask ourselves whether the chief reason of the difficulty does not lie in this, that the motions in question are habitually performed intelligently and consciously. Regarded as mere mechanisms, those of locomotion are no doubt more complicated than those of respiration or circulation, but the difference is one of degree, not of kind. And if the respiratory movements are so controlled and regulated by the automatic centre which governs them, that they adapt themselves perfectly to the varying requirements of the organism, there is no reason why we should hesitate in attributing to the centres which preside over locomotion powers which are somewhat more extended.

But perhaps the question has already presented itself to your minds, What does all this come to? Admitting that we are able to prove (1) that in the animal body, Product is always proportional to Process, and (2), as I have endeavoured to show you in the second part of my discourse, that Descartes' dream of animal automatism has been realised, what have we learnt thereby? Is it true that the work of the last generation is worth more than that of preceding ones?

If I only desired to convince you that during the last half-century there has been a greater accession of knowledge about the function of the living organism than during the previous one, I might arrange here in a small heap at one end of the table the physiological works of the Hunters, Spallanzani, Fontana, Thomas Young, Benjamin Brodie, Charles Bell, and others, and then proceed to cover the rest of it with the records of original research on physiological subjects since 1831, I should find that, even if I included only genuine work, I should have to heap my table up to the ceiling. But I apprehend this would not give us a true answer to our question. Although, etymologically, Science and Knowledge mean the same thing, their real meaning is different. By science we mean, first of all, that knowledge which enables us to sort the things known according to their true relations. On this ground we call Haller the father of physiology, because, regardless of existing theories, he brought together into a system all that was then known by observation or experiment as to the processes of the living body. But in the "Elementa Physiologiæ" we have rather that out of which science springs than science itself. Science can hardly be said to begin until we have by experiment acquired such a knowledge of the relation between events and their antecedents, between processes and their products, that in our own sphere we are able to forecast the operations of nature, even when they lie beyond the reach of direct observation. I would accordingly claim for physiology a place in the sisterhood of the sciences, not because so large a number of new facts have been brought to light, but because she has in her measure acquired that gift of prevision which has been long enjoyed by the higher branches of natural philosophy. In illustration of this I have endeavoured to show you that every step of the laborious investigations undertaken during the last thirty years as to the process of nutrition, has been inspired by the previsions of J. R. Mayer, and that what we have learnt with so much labour by experiments on animals is but the realisation of conceptions which existed two hundred years ago in the mind of Descartes as to the mechanism of the nervous system. If I wanted another example I might find it in the previsions of Dr. Thomas Young as to the mechanism of the circulation, which for thirty years were utterly disregarded, until, at the epoch to which I have so often adverted, they received their full justification from the experimental investigations of Ludwig.

But perhaps it will occur to some one that if physiology founds her claim to be regarded as a science on her power of anticipating the results of her own experiments, it is unnecessary to make experiments at all. Although this objection has been frequently heard lately from certain persons who call themselves philosophers, it is not very likely to be made seriously here. The answer is, that it is contrary to experience. Although we work in the certainty that every experimental result will come out in accordance with great principles (such as the principle that every plant or animal is both, as regards form and function, the outcome of its past and present conditions, and that in every vital process the same relations obtain between expenditure and product as hold outside of the organism), these principles do little more for us than indicate the direction in which we are to proceed. The history of science teaches us that a general principle is like a ripe seed, which may remain useless and inactive for an indefinite period, until the conditions favourable to its germination come into existence. Thus the conditions for which the theory of animal automatism of Descartes had to wait two centuries, were (1) the acquirement of an adequate knowledge of the structure of the animal organism, and (2) the development of the sciences of physics and chemistry; for at no earlier moment were these sciences competent to furnish either the knowledge or the methods necessary for its experimental realisation; and for a reason precisely similar Young's theory of the circulation was disregarded for thirty years.

I trust that the examples I have placed before you to-day may have been sufficient to show that the investigators who are now working with such earnestness in all parts of the world for the advance of physiology, have before them a definite and well-understood purpose, that purpose being to acquire an exact knowledge of the chemical and physical processes of animal life, and of the self-acting machinery by which they are regulated for the general good of the organism. The more singly and straightforwardly we direct our efforts to these ends, the sooner we shall attain to the still higher purpose—the effectual application of our knowledge for the increase of human happiness.

The Science of Physiology has already afforded her aid to the Art of Medicine in furnishing her with a vast store of knowledge obtained by the experimental investigation of the action of remedies and of the causes of disease. These investigations are now being carried on in all parts of the world with great diligence, so that we may confidently anticipate that during the next generation the progress of pathology will be as rapid as that of physiology has been in the past, and that as time goes on the practice of medicine will gradually come more and more under the influence of scientific knowledge. That this change is already in progress we have abundant evidence. We need make no effort to hasten the process, for we may be quite sure that, as soon as science is competent to dictate, art will be ready to obey.

SECTION F

GEOGRAPHY

Opening Address by Sir Joseph D. Hooker, C.B., K.C.S.I., F.R.S., &c., President of the Section

On Geographical Distribution

It has been suggested that a leading feature of the sectional addresses to be delivered on the occasion of this, the fiftieth anniversary of the meetings of the British Association, should be a review of the progress made during the last half century in the branches of knowledge which the sections respectively represent.

It has further been arranged that, at so auspicious an epoch, the sections should, when possible, be presided over by past Presidents of the Association. This has resulted in almost every sectional chair being occupied by a President eminent as a cultivator of the science with which his section will be engaged, though not the one I have the honour of filling, which, from the fact of there being no professed geographer amongst the surviving past Presidents, has been confided to an amateur.

Under these circumstances I should be untrue to myself and to you, if I presumed to address you as one conversant with geography in any extended signification of the word, or if I attempted to deal with that important and attractive branch of it, topographical discovery, which claims more or less exclusively the time and attention of the geographers of this country. It is more fitting for me, and more in keeping with the objects of this Association, that I be allowed to discourse before you on one of the many branches of science the pursuit of which is involved in the higher aims of geographers, and which, as we are informed by an accomplished cultivator of the science, are

integral portions of scientific geography.[1] Of these none is more important than that of the distribution of animals and plants, which further recommends itself to you on this occasion from being a subject that owes its great progress during the last half-century as much to the theories advanced by celebrated voyagers and travellers as to their observations and collections.

Before, however, I proceed to offer you a sketch of the progress made during the lifetime of the Association in this one branch, I must digress to remind you, however briefly, of the even greater advances made in others, in many cases through the direct or indirect instrumentality of the Association itself, acting in concert with the Royal and with the Royal Geographical Societies.

In topography the knowledge obtained during this half century has been unprecedently great. The veil has been withdrawn from the sources of the Nile, and the lake systems of Central Africa have been approximately localised and outlined. Australia, never previously traversed, has been crossed and recrossed in various directions. New Guinea has had its coasts surveyed, and its previously utterly unknown interior has been here and there visited. The topography of Western China and Central Asia, which had been sealed books since the days of Marco Polo, has been explored in many quarters. The elevations of the highest mountains of both hemispheres have been accurately determined, and themselves ascended to heights never before attained; and the upper regions of the air have been ballooned to the extreme limit beyond which the life-sustaining organs of the human frame can no longer perform their functions. In hydrography the depths of the great oceans have been sounded, their shores mapped, and their physical and natural history explored from the Equator to beyond both polar circles. In the Arctic regions the highest hitherto attained latitudes have been reached; Greenland has been proved to be an island; and an archipelago has been discovered nearer to the Pole than any other land. In the Antarctic regions a new continent has been added to our maps, crowned with one of the loftiest known active volcanoes, and the Antarctic ocean has been twice traversed to the 79th parallel. Nor have some of the negative results of modern exploration been less important, for the Mountains of the Moon and many lesser chains have been expunged from our maps, and there are no longer believers in the inland sea of Australia or in the open ocean of the Arctic pole. Of these and many others of the geographical discoveries of the last half-century full accounts will be laid before you, prepared for this section by able geographers; of whom Mr. Markham will contribute Arctic discovery; Sir Richard Temple, Asiatic; Lieut.-Col. Sir James Grant and Mr. H. Waller, African; Mr. Moseley, Australian; Mr. Trelawny Saunders, Syrian (including the Holy Land); the Hydrographer of the Admiralty will undertake the great oceans, and Mr. F. Galton will discuss the improvements effected in the instruments, appliances, and methods of investigation employed in geographical researches.

Of other branches of science which are auxiliary to scientific geography, the majority will be treated of in the sections of the Association to which they belong; but there are a few which I must not, in justice to the geographers who have so largely contributed to their advance, leave unnoticed.

Such is Terrestrial Magnetism,[2] which had as its first investigators two of our earliest voyagers, the ill-fated Hudson and Halley, who determined the magnetic dip in the north polar and tropical regions respectively. Theirs were the precursors of a long series of scientific expeditions, during which the dipping needle was carried almost from Pole to Pole, and which culminated in the establishment, mainly under the auspices of this Association, of the magnetic survey of Great Britain, of fixed magnetic observatories in all quarters of the globe, and of the Antarctic expedition of Sir James Ross, who, since the foundation of the Association, planted the dipping needle over the northern Magnetic Pole, and carried it within 200 miles of the southern one.

[1] Major-General Strachey, in a lecture delivered before the Royal Geographical Society (*Proceedings*, vol. xxxi. p. 179, 1877), discusses, with just appreciation and admirable clearness, the interdependence of the sciences which enter into the study and aims of scientific geography, and which he enumerates under fourteen heads. This lecture contains the ablest review of the subject known to me. It might very well be entitled "The whole duty of the Geographer." Every traveller's outfit should include a copy of it, and one should accompany every prize given by the Geographical Society to students for proficiency in geographical knowledge.

[2] The subject of an able lecture "On the Magnetism of the Earth," delivered before the Royal Geographical Society by the Hydrographer of the Admiralty (*Proceedings*, vol. xxi. p. 20, 1876).

Nor is the geography of this half century less indebted to physicists, geologists, and naturalists. It is to a most learned traveller, and naturalist, Von Baer, that the conception is due that the westward deflection of all the South Russian rivers is caused by the revolution of the globe on its axis.[1] It was a geologist, Ramsay, who explained the formation of so many lake beds in mountain regions by the gouging action of glaciers. It was a physicist and mountaineer, Tyndal, who discovered those properties of ice upon which the formation and movement of glaciers depend. The greatest of naturalist-voyagers, Darwin, within the same half-century has produced the true theory of coral reefs and atolls, showed the relations between volcanic islands and the rising and sinking of the bottom of the ocean, and proved that along a coast line of 2480 miles the southern part of the continent of South America has been gradually elevated from the sea level to 600 feet above it. Within almost the same period Poulett Scrope and Lyell have revolutionised the theory of the formation of volcanic mountains, showing that these are not the long-taught upheavals of the crust of the earth, but are heaped up deposits from volcanic vents, and they have largely contributed to the abandonment of the venerable theory that mountain chains are sudden up-thrusts. Within the same period, the theory of the great oceans having occupied their present positions on the globe from very early geological times was first propounded by Dana,[2] the companion of Wilkes in his expedition round the world, and is supported by Darwin and by Wallace.

In Meteorology the advance is no less attributable to the labours of voyagers and travellers. The establishment of the Meteorological Office is due to the energy and perseverance of a great navigator, the late Admiral Fitzroy.

Another domain of knowledge that claims the strongest sympathies of the geographer is Anthropology. It is only within the last quarter of a century that the study of man under his physical aspect has been recognised as a distinct branch of science, and represented by a flourishing society, and by annual international congresses.

I must not conclude this notice without a passing tribute to a department of geography that has occupied the attention of too few of its cultivators. I mean that of literary research. Nevertheless, in this too the progress has been great; and I need only mention the publications of the Hakluyt Society, and two works of prodigious learning and the greatest value, "The Book of Marco Polo, the Venetian,"[3] and "A History of Ancient Geography,"[4] to prove to you that one need not to travel to new lands to be a profound and sagacious geographer.

I have asked you to accept the geographical distribution of organic beings as the subject which I have chosen for this address. It is the branch with which I am most familiar; it illustrates extremely well the interdependence of those sciences which the geographer should study, and as I have before observed, its progress has been in the main due to the labours of voyagers and travellers.

In the science of distribution, Botany took the lead. Humboldt, in one of his essays,[5] says that the germ of it is to be found in an idea of Tournefort, developed by Linnæus. Tournefort was a Frenchman of great learning, and, moreover, a great traveller. He was sent by the King of France in 1700 to explore the islands of Greece and mountains of Armenia, in the interests of the Jardin des Plantes, and his published narrative is full of valuable matter on the people, antiquities, and natural productions of the countries he visited. The idea attributed to him by Humboldt,[6] is that in ascending mountains we meet successively with vegetations that represent those of successively higher latitudes; upon which Humboldt observes: "Il ne fallut pas une grande sagacité pour observer que sur les pentes des hautes montagnes de l'Arménie, des végétaux des différentes latitudes se suivent comme les climats superposés l'un sur les autres"; but he goes on to remark, "cette idée de Tournefort developpée par Linné dans deux dissertations intéressantes (Stationes et Coloniæ Plantarum), renferment cependant le germe de la Géographie

[6] I have been unable to find any such idea expressed in Tournefort's works. Edward Forbes, however, also attributes the idea to Tournefort (Memoirs of the Geology Survey, vol i. p. 351).

Botanique." Tournefort's idea was, however, an advanced one for the age he lived in, and should not be judged by the light of the knowledge of a succeeding century. He had no experience of other latitudes than the few intervening between Paris and the Levant. Humboldt himself did not suspect the whole bearing of the idea on the principles of geographical distribution, and that the parallelism between the floras of mountains and of latitudes was the result of community of descent of the plants composing the floras, not that it was brought about by physical causes. The idea of the early part of the eighteenth century is, when rightly understood, found to be the forerunner of the matured knowledge of the middle of the nineteenth.

The labours of Linnæus, himself a traveller, and whose narratives give him high rank as such, paved the way to a correct study of botanical geography. Before his time little or no attention was paid to the topography of plants, and he was the first to distinguish, to lay down rules, and to supply models for these two important elements in their life-history—namely, their habitats or topographical localisation, and their stations, or the physical nature of their habitats. In his "Stationes Plantarum,"[1] Linnæus defines with precision twenty-four stations characterised by soil, moisture, exposure, climate, &c., which, with comparatively slight modifications and improvements, have been adopted by all subsequent authorities. Nor, indeed, was any marked advance in this subject made, till geological observation and chemical analysis supplemented its shortcomings. In his essay "De coloniis plantarum," published fourteen years after the "Stationes,"[2] he says, "Qui veram cunque et solidam plantarum scientiam aucupatur, patriam ipsarum ac sedem cujusque propriam haud sane ignorabit," and he proceeds to give an outline of the distribution of certain plants on the globe, according to climate, latitude, &c., and to indicate their means of transport by winds, birds, and other agencies. India (meaning the tropics of both worlds) he characterises as the region of palms; the temperate latitudes, of herbaceous plants; the northern, of mosses, algæ, and coniferæ; and America, of ferns;—thus preparing the way for the next great generaliser in the field.[3]

This was the most accomplished and prolific of modern travellers, Humboldt, who made botany a chief pursuit during all his journeys, and who seems, indeed, to have been devoted to it from a very early age. His first work was a botanical one, the "Flora Friburgensis," and we have it on his own authority that three years before its publication, when he was only just of age (in 1790) he communicated to his friend G. Förster, the companion of Cook in his second voyage, a sketch of a geography of plants. It was not, however, till his return from America that his first essay on Botanical Geography[4] appeared, which at once gave him a very high position as a philosophical naturalist. Up to the period of its appearance there had been nothing of the kind to compare with it for the wealth of facts, botanical, meteorological, and hypsometrical, derived from his own observations, from the works of travellers and naturalists, and from personal communication with his contemporaries, all correlated with consummate skill and discussed with that lucidity of exposition of which he was a master. The great feature of this essay is the exactness of the methods employed for estimating the conditions under which species, genera, and families are grouped geographically, and the precision with which they are expressed.

This was succeeded in 1815, and subsequently, by four other essays on the same subject. Of these the most valuable is the "Prolegomena,"[5] in which he dwells at length on the value of numerical data, and explains his "Arithmeticæ botanices," which consists in determining the proportion which the species of certain large families or groups of families bear to the whole number of species composing the floras in advancing from the Equator to the Poles, and in ascending mountains. Some kinds of plants, he says, increase in numbers relatively to others in proceeding from the Equator to the Poles, as ferns, grasses, amentiferous trees, &c.; others decrease, as Rubiaceæ, Malvaceæ, Compositæ, &c.; whilst others still, as Labiatæ, Cruciferæ, &c., find their maximum in temperate regions, and decrease in both directions. He adds that it is only by accurately measuring this decrease or increase that laws can be established, when it is found that these present constant relations to parallels of temperature.[1] Furthermore, he says that in many cases the whole number of plants contained in any given region of the globe may be approximately determined by ascertaining the number of species of such families.

The importance of this method of analysing the vegetation of a country in researches in geographical botany is obvious, for it affords the most instructive method of setting forth the relations that exist between a flora and its geographical position and climatal conditions.

Humboldt's labours on the laws of distribution were not limited to floras, they included man and the lower animals, cultivated and domesticated, as well as native; they may not be works of the greatest originality, but they show remarkable powers of observation and reflection, astonishing industry, conscientious exactitude in the collection of data, and sagacity in the use of them; he is indisputably the founder of this department of geographical science.

No material advance was made towards improving the laws of geographical distribution[2] so long as it was believed that the continents and oceans had experienced no great changes of surface or of climate since the introduction of the existing assemblages of animals and plants. This belief in the comparative stability of the surface was first dispersed by Lyell, who showed that a fauna may be older than the land it inhabits. To this conclusion he was led by the study of the recent and later tertiary molluscs of Sicily, which he found had migrated into that land before its separation from the continent of Italy. Just, he adds, as the plants and animals of the Phlegræan fields had colonised Monte Nuovo since that mountain was thrown up in the sixteenth century; whence, he goes on to say, we are brought to admit the curious result, that the fauna and flora of Val de Noto, and of some other mountain regions of Italy, are of higher antiquity than the country itself, having not only flourished before the lands were raised from the deep, but even before they were deposited beneath the waters.[3] The same idea occurred to Darwin, who, alluding to the very few species of living quadrupeds which are altogether terrestrial in habit, that are common to Asia and America, and to these few being confined to the extreme frozen regions of the North, adds, "We may safely look at this quarter (Behring's Straits), as the line of communication (now interrupted by the steady progress of geological change), by which the elephant, the ox, and the horse entered America, and peopled its wide extent."[4]

The belief in the stability of climatal conditions during the lifetime of the existing assemblages of animals and plants was also dispelled by the discovery, throughout the northern temperate regions of the old and new worlds, of Arctic and boreal plants on all their mountains, and of these fossilised on their lowlands, and which discoveries led to the recognition of the glacial period and glacial ocean.

The first and boldest attempt to press the results of geological and climatal changes into the service of botanical and zoological geography was that of the late Edward Forbes, a naturalist of genius, who, like Tournefort, chose the Levant as the field for his early labours. In the year 1846, Forbes communicated a paper to the Natural History section of this Association, on the distribution of endemic plants, especially those of the British

[2] *Ibid.* vol. viii. p. 1, 1768.

[3] Between the dates of the writings of Linnæus and Humboldt, two notable works on geographical distribution appeared. One by Frid. Stromeyer ("Commentatio inauguralis sistens Historiæ Vegetabilium Geographicæ specimen," Göttingen, 1800), is an excellent syllabus of the points to be attended to in the study of distribution, but without examples; the other is a too general work by Zimmermann, entitled, "Specimen Zoologiæ Geographicæ, Quadrupedum Domicilia et Migrationes sistens," Lugd. Bat. 1777, which he followed by "Geographische Geschichte des Menschen und der allgemein verbreiteten vierfüssigen Thiere, nebst einer hieher gehörigen zoologischen Weltcharte, Leipzig, 1778-1783."

[4] "Essai sur la Géographie des Plantes," par A. de Humboldt et Aimé Bonpland; rédigée par A. de Humboldt, lu à la Classe des Sc. Phys. et Math. de l'Institut Nationale, 17 Nivôse de l'An 13, 1805.

[5] "De Distributione Geographica plantarum secundum Cœli temperiem et altitudinem Montium, Prolegomena." This appeared in quarto in the first volume of the "Nova Genera et Species Plantarum" in 1815, and separately in an octavo form in 1817. Humboldt's other works on geographical distribution are "Notationes ad Geographiam Plantarum spectantes," 1815; "Ansichten der Natur," 1808, and ed. 2, 1827; "Nouvelles Recherches sur les lois que l'on observe dans la Distribution des formes végétales" (1816); and an article with a similar title in the "Dictionnaire des Sciences Naturelles," vol. xviii p. 422, 1820.

[1] Humboldt's isothermal lines and laws of geographical distribution are obviously the twin results of the same researches, one physical, the other biological.

[2] I do not hereby imply that no progress was made in the knowledge of the facts of distribution, for, over and above many treatises on the distribution of the plants of local floras, there appeared, in 1816, Schouw's "Dissertatio de sedibus plantarum originariis"; which was followed in 1822 by his excellent "Grundtrack til el almendelig Plante-Geographie," of which the German edition is entitled, "Grundzüge einer allgemeinen Pflanzengeographie."

[3] "Principles of Geology," ed. 3, vol. iii. p. 376, 1834.

[4] *Journal of Researches in Geology and Natural History, &c.*, p. 151 1839.

Islands, considered with regard to geological changes.[1] In this paper the British flora is considered to consist of assemblages of plants from five distinct sources, which, with the exception of one, immigrated during periods when the British Isles were united to the continent of Europe, and have remained more or less localised in England, in Scotland, or in Ireland. Of these he considered the Pyrenean assemblage, which is confined to the west of Ireland, to be the oldest, and to have immigrated, after the eocene period, along a chain of now submerged mountains, that extended across the Atlantic from Spain to Ireland, and indeed formed the eastern boundary of an imaginary continent of miocene age, which extended to the Azores Islands, and beyond them. This, the "Atlantis" of speculative geologists, has long since been abandoned. The second assemblage is of plants characteristic of the South-West of France, which now prevail in Devon, Cornwall, and the Channel Islands; their immigration he assigns to a miocene date, probably corresponding to the red crag. The third assemblage is of plants of the North-East of France, which abound in the chalk districts of the South-Eastern counties of England; their immigration is referred to the era of the mammaliferous crag. The fourth is of Alpine plants now found on the mountains of Scotland, Wales, and England; these were introduced mainly by floating ice from Scandinavia during the glacial period, when the greater part of the British Isles were submerged, its mountain tops forming part of a chain of islands in the glacial sea that extended to the coast of Norway; this was during the newer pliocene period. Lastly, the Germanic plants were introduced during the upheaval of the British Islands from the glacial ocean, and as the temperature was gradually increasing; these are spread over the whole islands, though more abundant on the Eastern side. At the commencement of this immigration England was supposed to be continuous with the Germanic plains, from which it was subsequently severed by the formation of the English Channel. Also, at the commencement of this immigration, Ireland was assumed to be continuous with England, to be early severed by the formation of the Irish Sea; which severance, by interrupting the migration of Germanic types, accounts for the absence of so many British animals in the sister island.

I have thus briefly related Forbes' views, to show how profoundly he was impressed with the belief that geographical and climatal conditions were the all-powerful controllers of the migrations of animals and plants. Forbes was the reformer of the science of geographical distribution.[2]

Before the publication of the doctrine of the origin of species by variation and natural selection, all reasoning on their distribution was in subordination to the idea that these were permanent and special creations; just as, before it was shown that species were often older than the islands and mountains they inhabited, naturalists had to make their theories accord with the idea that all migration took place under existing conditions of land and sea. Hitherto the modes of dispersion of species, genera, and families had been traced; but the origin of representative species, genera, and families remained an enigma[3]; these could be explained only by the supposition that the localities where they occurred presented conditions so similar that they favoured the creation of similar organisms, which failed to account for representation occurring in the far more numerous cases where there is no discoverable similarity of physical conditions, and of their not occurring in places where the conditions are similar. Now under the theory of modification of species after migration and isolation, their representation in distant localities is only a question of time and changed physical conditions. In fact, as Darwin well sums up, all[1] the leading facts of distribution are clearly explicable under this theory; such as the multiplication of new forms; the importance of barriers in forming and separating zoological and botanical provinces; the concentration of related species in the same area; the linking together under different latitudes of the inhabitants of the plains and mountains, of the forests, marshes, and deserts, and the linking of these with the extinct beings which formerly inhabited the same areas; and the fact of different forms of life occurring in areas having nearly the same physical conditions.

With the establishment of the doctrine of the orderly evolution of species under known laws, I close this list of those recognised principles of the science of geographical distribution which must guide all who enter upon its pursuit. As Humboldt was its founder, and Forbes its reformer, so we must regard Darwin as its latest and greatest lawgiver. With their example, and their conclusions to guide, advance becomes possible whenever discovery opens new paths, or study and reflection retraverse the old ones.

And it was not long before palæontology brought to the surface new data for the study of the present and past physical geography of the globe.

This was the discovery in Arctic latitudes of fossil plants whose existing representatives are to be found only in warm temperate ones. To Arctic travellers and voyagers this discovery is wholly due. Of these I believe I am correct in saying that Sir John Richardson was the earliest, for he, in the year 1848, when descending the McKenzie River to the Polar Sea in search of the Franklin Expedition, found in lat. 65° N. beds of coal, besides shales full of leaves of forest-trees belonging to such genera as the maple, poplar, taxodium, oak, &c. In the narrative of his journey[2] Richardson mentions these fossils, and figures some of them; and in a subsequent work[3] he speaks of them as "leaves of deciduous trees belonging to genera which do not in the present day come so far north on the American continent by ten or twelve degrees of latitude." This discovery was followed, in 1853, by the still more remarkable one, by Capt. M'Clure and Sir Alexander Armstrong (during another search for Sir John Franklin), of pine cones and acorns imbedded in the soil of Banksland, in lat. 75° N., at an elevation of 300 feet above the sea level. And again in 1854 Dr. Lyall found extensive accumulations of similar fossils near Discoe in Greenland (lat. 70° N.), during the return of Sir Edward Belcher's searching expedition. Nor are these fossils confined to America: they have been found in Spitzbergen, in Siberia, and in many other localities within the Polar area as well as south of it, proving that forests of deciduous trees, in all respects like those of the existing forests of the warm temperate regions, approached to within ten degrees of the Pole. The first of these collections critically examined was Dr. Lyall's; it was communicated to Prof. Heer of Zurich, the highest authority on the flora of the Tertiary period, and described by him,[4] as were also subsequently all the other collections brought from the Arctic regions.[5]

The examination of these fossil leaves revealed the wonderful fact that, not only did they belong to genera of trees common to the forests of all the three northern continents, such as planes, beeches, ashes, maples, &c., but that they also included what are now extremely rare and even local genera, as sequoia, liquid-amber, magnolia, tulip-trees, gingkos, &c., proving that the forests were of a more mixed character than any now existing. These results opened up a new channel for investigating the problem of distribution, and the first naturalist to enter it as a botanist, Dr. Asa Gray, who pursued it with brilliant results, embodied in a series of memoirs on the vegetation of the United States of America, and of which my notice must be most brief.

When studying the collections of Japanese plants brought by the officers of Wilkes' expedition, Dr. Gray found cumulative evidence of the strong affinity between the flora of Eastern Asia

[1] *British Association Reports*, 1845, pt. ii. p. 67, and *Annals and Magazine of Natural History*, vol. xvi. p. 126. This the author followed by a much fuller exposition of the subject, which appeared in the *Memoirs of the Geological Survey of the United Kingdom*, vol. i. p. 336 (1846), entitled "On the Connexion between the distribution of the existing flora and fauna of the British Isles, and the geological changes which have affected their area, especially during the epoch of the northern drift." After many years interval I have re-read this Memoir with increased pleasure and profit. The stores of exact information which he collected concerning the plants, the animals, and the geology of Europe and North America, appear to me to be no less remarkable than the skill with which he correlated them and educed from the whole so many very original and in great part incontrovertible conclusions.

[2] I cannot dismiss the subject of the geography of the British flora without an allusion to the labours of Hewett Cottrell Watson, who, after a life devoted to the topography of British plants, was laid in the grave only a month ago. Watson was the first botanist who measured the altitudinal range of each species, and, by a rigidly statistical method, traced their distribution in every county, and grouped them according to their continental affinities, as well as by the physical conditions of their habitats.

[3] The representation of species Forbes alludes to as "an accident . . . which has hitherto not been accounted for" (*Mem.* Geol. Survey, vol. i. p. 351).

[1] Of the many pre-Darwinian writers on distribution who advocated the Lamarckian doctrine of evolution, I am not aware of any who suggested that it would explain the existence of representative species, or indeed any other of the phenomena of distribution. Von Baer, however, in the very year of the publication of the first edition of the "Origin of Species," expressed his conviction, chiefly grounded on the laws of geographical distribution, that forms now specifically distinct have descended from a single parent form. See "Origin of Species," ed. 5, Historical Sketch, p. 23.

[5] "Flora fossilis Arctica."

and Eastern North America, to the exclusion of the western half of that continent; and also that Europe and Western Asia did not share in this affinity. But what especially attracted his attention was, that this affinity did not depend only on a few identical or representative genera, but upon many endemic genera of exceptional character, and often consisting of only two almost identical species. This led to a rigorous comparison of those plants with the fossils from the Arctic regions whose affinities had been determined by Heer, and with others which had been meanwhile accumulating in the United States, and had been described by Lesquereux; and the result was what I may call an abridged outline history of the flora of North America in its relations to the physical geography of that country, from the Cretaceous to the present time.

The latest researches which have materially advanced our knowledge of the laws of distribution are those of Prof. Blytt of Christiania. His essay on "The Immigration of the Norwegian Flora during alternately Rainy and Dry Periods" has for its object to define and localise the various assemblages of plants of which that flora is composed, and to ascertain their mother-country and the sequence of their introduction. The problem is that of Prof. Forbes, which I have already described to you, only substituting Norway for the British Isles. Both these authors invoke the glacial period to account for the dispersion of Arctic plants, both deal with a rising land, both assume that immigration took place over land; but Prof. Blytt finds another and most powerful controlling agent, in alternating periods of greater moisture and comparative drought, of which the Norwegian peat bogs afford ample proof. These bogs were formed during the rise of the land, as the cold of the glacial period declined. They are found at various heights above the sea in Norway; the most elevated of them are of course the oldest, and contain remains of the earliest immigrants. The lowest are the newest, and contain remains of the latest introduced plants only. The proofs of the alternating wet and dry seasons rest on the fact that the different layers of peat in each bog present widely different characters, contain the remains of different assemblages of plants, and these characters recur in the same order in all the bogs. First there is a layer of wet spongy peat, with the remains of bog-mosses and aquatic plants; this gradually passes upwards into a layer of dry soil containing the remains of many land plants, and prostrate trunks of trees, showing that the country was forested. To this succeeds wet spongy peat as before, to be again covered with dry peaty soil and tree trunks, &c., and so on. From an examination of the plant remains in these formations Prof. Blytt draws the following conclusions:—

The Norwegian flora began with an immigration of Arctic plants during a dry period, evidence of which he finds in the presence of the remains of these beneath the lowest layer of peat. As the climate became warmer and the land rose, a rainy period set in, accompanied by an immigration of sub-Arctic plants (juniper, mountain ash, aconites, &c.), which to a great extent replaced the Arctic flora, which is impatient of great wet. This was the period of the first peat-bog formation. It was followed by a dry period, during which the bogs gradually dried up; while with the increasing warmth, deciduous trees and their accompanying herbaceous vegetation were introduced. The succeeding rainy season produced a second peat-formation, killing and burying the deciduous trees, the increasing warmth at the same time bringing in the Atlantic flora, characterised by the holly, foxglove, and other plants now confined in Norway to the rainy Atlantic coast. To this succeeded a third period of drought, when the bogs dried up, and pine-forests with their accompanying plants immigrated into Norway, to be in like manner destroyed and buried by bog earth during the next following rainy period; and it was during these last alternations that the subboreal plants now affecting the lowest south-eastern districts of Norway were introduced; and the sub-Atlantic plants, the most southern of all the types which are confined to the extreme south of the country.

It would be premature to regard all Prof. Blytt's recurrent periods as irrefragably established, or his correlations of these with the several floras as fully proved; but there is no doubt, I think, that he has brought forward a *vera causa* to account for the alternation of dry country with wet country plants in Norway, and one that must have both actively promoted the first introduction of these into that country, as also influenced their subsequent localisation. It would strengthen Prof. Blytt's conclusions very much if his alternating periods of rain and drought should be found to harmonise with Mr. Croll's recurrent astronomical periods, and with Mr. Geikie's fluctuations of temperature during the decline of the Glacial epoch: so would also the finding in the bogs of Scotland a repetition of the conditions which obtain in those of Norway; and there are so very many points of resemblance in the physical geography and vegetation of these two countries that I do not doubt a comparison of their peat formations would yield most instructive results.

Thus far all the knowledge we have obtained of the agents controlling geographical distribution have been derived from observations and researches on northern animals and plants, recent and tertiary. Turning now to the southern hemisphere, the phenomena of distribution are much more difficult of explanation. Geographically speaking, there is no Antarctic flora except a few lichens and sea-weeds. The plants called Antarctic,[1] from their analogy with the Arctic, are very few in number, and nowhere cross the 62° of south latitude. They are, in so far as they are endemic, confined to the southern islands of the great southern ocean, and the mountains of South Chili, Australia, Tasmania, and New Zealand; whilst the few non-endemic are species of the nearest continents, or are identical with temperate northern or with sub-Arctic or even Arctic species. Like the Arctic flora, the Antarctic is a very uniform one round the globe, the same species, in many cases, especially the non-endemic, occurring on every island, though there are sometimes thousands of miles of ocean between the nearest of these. And, as many of the island plants reappear on the mountains above mentioned, far to the north of their island homes, it is inferred on these grounds, as well as on astronomical and geological, that there was a glacial period in the southern temperate zone as well as in the northern.

The south temperate flora is a fourfold one. South America, South Africa, Australia, and New Zealand contain each an assemblage of plants differing more by far amongst themselves than do the floras of Europe, North Asia, and North America; they contain, in fact, few species in common, except the Antarctic ones that inhabit their mountains. These south temperate plants have their representative species and genera on the mountains of the tropics, each in their own meridian only, and there they meet immigrants from all latitudes of the northern hemisphere. Thus the plants of Fuegia extend northward along the Andes, ascending as they advance. Australian genera reappear on the lofty mountain of Kini-balu in Borneo; New Zealand ones on the mountains of New Caledonia; and the most interesting herbarium ever brought from Central Africa, that of Mr. Joseph Thomson, from the highlands of the lake districts, contains many of the endemic genera, and even species of the Cape of Good Hope. Nor does the northern representation of the south temperate flora cease within the tropics; it extends to the middle north temperate zone; Chilian genera reappearing in Mexico and California; South African in North Africa, in the Canary Islands, and even in Asia Minor[2]; and Australian in the Khasia Mountains of East Bengal, in East China and Japan.

So too there is a representation of genera in the southern temperate continents, feeble numerically compared to what the north presents, but strong in other respects. This is shown by the families of Proteaceæ, Cycadeæ, and Restiaceæ, abounding in South Africa and Australia alone, though not a single species or even genus of these families is common to the two countries; by New Zealand, with a flora differing in almost every element from the Chilian, yet having a few species of both calceolaria and fuchsia, genera otherwise purely American; whilst as regards Australia and New Zealand, it is difficult to say which are the most puzzling, the contrasts or the similarities which their animal and vegetable productions present.

These features of the vegetation of the south temperate and Antarctic regions, though they simulate those of the north temperate and Arctic, may not originate from precisely similar causes. In the absence of such evidence as the fossil animals and plants of the north affords,[3] there is no proof that the Ant-

[1] For accounts of the Antarctic flora see the "Botany" of the Antarctic Expedition of Sir James Ross, where the relations of the floras of the southern hemisphere with the Antarctic are discussed in introductory chapters.

[2] *Pelargonium Endlicherianum* in the Taurus is a remarkable instance.

[3] The only fossil leaves hitherto found in higher southern latitudes are those of beeches, closely allied to existing southern species, brought by Darwin from Fuegia. In one locality alone beyond the forest region of the south have fossil plants been found; there were silicified trunks of trees in lava beds of Kerguelen's Island (discovered by myself forty years ago). It is deeply to be regretted that searches for shales containing fossils were not

arctic plants found on the south temperate Alps, or the south temperate plants found in the mountains of the tropics, originated in the south; though this appears probable from the absence in the south of so many of the leading families of plants and animals of the north, no less than from the number of endemic forms the south contains. These considerations have favoured the speculation of the former existence, during a warmer period than the present, of a centre of creation in the Southern Ocean, in the form of either a continent or of an archipelago, from which both the Antarctic and southern endemic forms radiated. I have myself suggested continental or insular extension[1] as a means of aiding that wide dispersion of species over the Southern Ocean, which it is difficult to explain without such intervention; and the discovery of beds of fossil trunks of trees in Kerguelen's Island, testifies to that place having enjoyed a warmer climate than its present one.

The rarity in the existing Archipelago (Kerguelen's Island, the Crozets, and Prince Edward's Island) of any of the endemic genera of the south temperate flora, or of representatives of them, is, however, an argument against such land, if it ever existed, having been the birthplace of that flora; and there are two reasons for adopting the opposite theory, that the southern flora came from the north temperate zone. Of these, one is the number of northern genera and species (which, from their all inhabiting north-east Europe, I have denominated Scandinavian)[2] that are found in all Antarctic and south temperate regions, the majority of them in Fuegia, the flora of which country is, by means of the Andes, in the most direct communication with the northern one. The other is the fact I have stated above, that the several south temperate floras are more intimately related to those of the countries north of them than they are to one another.

And this brings me to the latest propounded theoretical application of the laws of geographical distribution. It is that recently advanced by Mr. Thiselton Dyer, in a lecture "On Plant Distribution as a Field of Geographical Research"[3]; wherein he argues that the floras of all the countries of the globe may be traced back at some time of their history to the northern hemisphere, and that they may be regarded in point of affinity and specialisation as the natural results of the conditions to which they must have been subjected during recent geological times, on continents and islands with the configuration of those of our globe. This hypothesis derives its principal support from the fact that many of the most peculiar endemic plants of the south have representatives in the north, some of them living and all of them in a fossil state, whilst the northern endemic forms have not hitherto been found fossil in the southern regions. So that, given time, evolution, continental continuity, changes of climate and elevations of the land, and all the southern types may be traced back to one region of the globe, and that one palæontology teaches us is the northern.

A very similar view has been held and published at the same time by Count Saporta,[4] a most eminent palæontologist, in a suggestive essay entitled "L'Ancienne Végétation Polaire." Starting from Buffon's thesis, that the cooling of the globe having been a gradual process, and the Polar regions having cooled first, these must have first become fit for organic life, Count Saporta proceeds to assume that the termination of the azoic period coincided with a cooling of the waters to the point at which coagulation of albumen does not take place, when organic life appeared in the water itself. I have discussed Count Saporta's speculations elsewhere[5]; it is sufficient here to indicate the more important ones as bearing upon distribution. These are that the Polar area was the centre of origination of all the successive phases of vegetation that have appeared on the globe, all being developed in the north; and that the development of flowering plants was enormously augmented by the introduction during the latter part of the secondary period of flower-feeding insects, which brought about cross-fertilisation.

It remains to allude briefly to the most important general works on distribution that have appeared since the foundation of this Association. Of these, the two which take the first rank are Prof. Alphonse de Candolle's "Géographie Botanique" and Mr. Wallace's "Geographical Distribution of Animals." Prof. de Candolle's work [1] appeared at a critical period, when the doctrine of evolution with natural selection had only just been announced, and before the great influence of geological and climatal changes on the dispersion of living species had been fully appreciated; nevertheless it is a great and truly philosophical work, replete with important facts, discussed with full knowledge, judgment, and scrupulous caution. Of its numerous valuable and novel features, two claim particular notice, namely, the chapters on the history of cultivated and introduced plants; and the further development of Humboldt's "Arithmeticæ Botanices," by taking into account the sums of temperatures as well as the maxima, minima, and means, in determining the amount of heat required to satisfy all the conditions of a plant's life, at the various periods of its existence, and especially the maturation of its seeds.

Of Mr. Wallace's great work, "The Geographical Distribution of Animals," I cannot speak with sufficient knowledge of the subject, and can only appreciate and echo the high praises accorded to it by zoologists for its scientific treatment of a vast subject.

The "Géographie Botanique" was followed by the late Dr. Grisebach's "Die Vegetation der Erde,"[2] which contains an admirable summary of the vegetation of the different regions of the globe as limited by their physical features, divested of all theoretical considerations.

For the largest treatment in outline of the whole subject of distribution, I must refer to the chapters of Darwin's "Origin of Species" which are devoted to it.

In reference to these and other works, very able and instructive discussions of the principles of geographical distribution are to be found in the presidential addresses delivered before the Linnean Society, in 1869, 1870, and 1872, by the veteran botanist, G. Bentham.

With Mr. Wallace's "Island Life" I must conclude this notice, and very fittingly, for besides presenting an admirable account of the origin and migrations of animals and vegetables in oceanic and continental islands, it contains a complete and comprehensive analysis of those past and present conditions of the globe, astronomical, geological, geographical, and biological, which have been the earlier and later directors and controllers of the ever-warring forces of organic nature. In this work Mr. Wallace independently advocates the view of the northern origin of both the faunas and floras of the world.

I conclude with the hope that I have made the subject of the distribution of organic life on the globe interesting to you as geographers, by showing on the one hand how much it owes its advance to the observations made and materials collected by geographical explorers, and on the other how greatly the student of distribution has, by the use he has made of these observations and materials, advanced the science of physical geography.

SECTION G

MECHANICAL SCIENCE

Opening Address by Sir W. Armstrong, C.B., D.C.L., LL.D., F.R.S., President of the Section

The astonishing progress which has been made in the construction and application of machinery during the half century which has elapsed since the nativity of the British Association for the Avancement of Science, is a theme which I might with much complacency adopt in this address, but instead of reviewing the past and exulting in our successes, it will be more profitable to look to the future and to dwell on our failures. It is but justice to say that by growing experience, by increasing facilities of manufacture, and by the exercise of much skill and ingenuity, we have succeeded in multiplying and expanding the applications of our chief motor, the steam-engine, to an extent that would have appeared incredible fifty years ago; but the

made either by the *Challenger* expedition or by the various "transit of Venus expeditions" that have recently visited this interesting island.

[5] Address of the President delivered at the anniversary meeting of the Royal Society of London, November 30, 1878.

[1] Prof. Alph. de Candolle divides his subject into botanical geography and geographical botany; the distinction is obvious and sound, but the two expressions have been so long used and regarded as synonymous, and as embracing both branches, that they cannot now be limited each to one. Perhaps the terms topographical botany and geographical botany would prove more acceptable designations.

[2] Published in 1872. Translated into French under the title of "La Végétation du Globe," by P. de Tchihachef, Paris, 1875.

gratulation inspired by this success is clouded by the reflection that the steam-engine, even in its best form, remains to this day a most wasteful apparatus for converting the energy of heat into motive power. Our predecessors of that period had not the advantage of the knowledge which we possess of the true nature of heat, and the conditions and limits affecting its utilisation. In their time heat was almost universally regarded as a fluid which, under the name of caloric, was supposed to lie dormant in the interstices of matter until forced out by chemical or mechanical means. Although Bacon, Newton, Cavendish, and Boyle all maintained that heat was only internal motion, and although Davy and Rumford not only held that view, but proved its accuracy by experiment, yet the old notion of caloric continued to hold its ground, until in more recent times Joule, Meyer, Codling, and others put an end to all doubt on the subject, and established the all-important fact that heat is a mode of motion having, like any other kind of motion, its exact equivalent in terms of work. By their reasonings and experiments it has been definitely proved that the quantity of heat which raises the temperature of a pound of water 1° Fahrenheit, has a mechanical value equal to lifting 772 lbs. one foot high, and that conversely the descent of that weight from that height is capable of exactly reproducing the heat expended.

The mechanical theory of heat is now universally accepted, although a remnant of the old doctrine is displayed in the continued use of the misleading term "latent heat." According to the new theory, heat is an internal motion of molecules capable of being communicated from the molecules of one body to those of another, the result of the imparted motion being either an increase of temperature, or the performance of work. The work may be either external, as where heat, in expanding a gas, pushes away a resisting body, or it may be internal, as where heat pulls asunder the cohering particles of ice in the process of liquefaction, or it may be partly internal and partly external, as it is in the steam engine, where the first effect of the heat is to separate the particles of water into vapour, and the second to give motion to the piston. Internal as well as external work may be reconverted into heat, but until the reconversion takes place, the heat which did the work does not exist as heat, and it is delusive to call it "latent heat." All heat problems are comprised under the three leading ideas of internal work, external work, and temperature, and no phraseology should be used that conflicts with those ideas.

The modern theory of heat has thrown new light upon the theory of the steam-engine. We now know what is the mechanical value in foot-pounds of the heat evolved in the combustion of one pound of coal. In practice we can determine how much of that heat is transmitted to the water in the boiler, and we are taught how to calculate the quantity which in the process of vaporisation takes the form of internal work. We can determine how much disappears in the engine in the shape of external work, including friction, and the remainder, with the exception of the trifling quantity saved in the feed-water, we know to be lost. Taking a good condensing engine as an example, we may roughly say that, dividing the whole heat energy into ten equal parts, two escape by the chimney, one is lost by radiation and friction, six remain unused when the steam is discharged, and only one is realised in useful work. It may be fully admitted that the greater part of the aggregate loss is inevitable; but are we to suppose that the resources of science, ingenuity, and skill have been exhausted in the attainment of so miserable a result? Nothing but radical changes can be expected to produce any great mitigation of the present monstrous waste, and without presuming to say what measures are practicable and what are not, I will briefly point out the directions in which amelioration is theoretically possible, and shall afterwards advert to the question whether we may hope to evade the difficulties of the steam-engine by resorting to electrical methods of obtaining power.

To begin with the loss which takes place in the application of heat to the boiler; why is it that we have to throw away, at the very outset of our operations, twice as much heat as we succeed in utilising in the engine? The answer is, that in order to force a transmission of heat from the fire to the water in the boiler, a certain excess of temperature over that of the water must exist in the furnace and flues, and the whole of the heat below the required excess must pass away unused, except the trifling portion of it which disappears in the production of draught. Further, that since we cannot avoid admitting the nitrogen of the air along with the oxygen, we have to heat a large volume of neutral gas which has no other effect than to rob the fire. Considering what efforts have been made to facilitate the transmission of the heat by augmenting the evaporative surface, and using thin tubes as flues, it is vain to expect any great result from further perseverance in that direction, and unless a method can be devised of burning the fuel inside instead of outside the apparatus, so as to use the heated gases conjointly with the steam as a working medium in the engine, a remedy appears to be hopeless. We already practise internal combustion in the gas-engine, and it is clear that with gaseous fuel, at all events, we could associate such a mode of combustion with the vaporisation of water. We may even regard a gun as an engine with internally-burnt fuel, and here I may remark that the action of heat in a gun is strictly analogous to that of heat in a steam-engine. In both cases the heat is evolved from chemical combination, and the resulting pressures differ only in degree. The gun is the equivalent of the cylinder, and the shot of the piston, and the diagrams representing the pressure exerted in the two cases bear a close resemblance to each other. While the powder is burning in the gun we have a nearly uniform pressure, just as we have in the cylinder while the steam is entering, and in both cases the uniform pressure is followed by a diminishing pressure, represented by the usual curve of expansion. If in the steam-engine we allowed the piston to be blown out it would act as a projectile, and if in the gun we opposed mechanical resistance to the shot, we might utilise the effect in a quieter form of motive power. But it is a remarkable fact that such is the richness of coal as a store of mechanical energy that a pound of coal, even as used in the steam-engine, produces a dynamic effect about five times greater than a pound of gunpowder burnt in a gun. I cannot, however, on this account encourage the idea that steam may be advantageously substitute for gunpowder in the practice of gunnery.

And now to turn from the fire which is the birthplace of the motive energy, let us follow it in the steam, to the condenser, where most of it finds a premature tomb. From the point at which expansion commences in the cylinder the temperature and pressure of the steam begin to run down, and if we could continue to expand indefinitely, the entire heat would be exhausted, and the energy previously expended in separating the water into steam would be wholly given up in external effect; but this exhaustion would not be complete until the absolute zero of temperature was reached (viz. 461° below the zero of Fahrenheit). I do not mean to say that an ideally perfect engine necessarily involves unlimited expansion, seeing that if instead of discharging the steam at the end of a given expansion, we made the engine itself do work in compressing it, we might, under the conditions of Carnot's reversible cycle, so justly celebrated as the foundation of the theory of the steam-engine, recommence the action with all the unutilised heat in an available form. But an engine upon this principle could only give an amount of useful effect corresponding to the difference between the whole work done by the engine, and that very large portion of it expended in the operation of compression, and this difference viewed in relation to the necessary size of the engine, would be quite insignificant, and would in fact be wholly swallowed up in friction. Carnot did not intend to suggest a real engine, and his hypothesis therefore takes no cognisance of losses incident to the application of an actual fire to an actual boiler. His ideal engine is also supposed to be frictionless, and impervious to heat except at the point where heat has to be transmitted to the water, and there the condition of perfect conduction is assumed. In short an engine which would even approximately conform to the conditions of Carnot's cycle is an impossibility, and a perfect steam-engine is alike a phantom whether it be sought for in the cyclical process of Carnot, or under the condition of indefinite expansion. Practically we have to deal with a machine which, like all other machines, is subject to friction, and in expanding the steam we quickly arrive at a point at which the reduced pressure on the piston is so little in excess of the friction of the machine as to render the steam not worth retaining, and at this point we reject it. In figurative language we take the cream off the bowl and throw away the milk. We do save a little by heating the feed water, but this gain is very small in comparison with the whole loss. What happens in the condenser is, that all the remaining energy which has taken the form of internal work is reconverted into heat, but it is heat of so low a grade that we cannot apply it to the vaporisation of water. But although the heat is too low to vaporise water it is not too low to vaporise Ether. If instead of condensing by the external application of water we did so by the similar application of ether, as proposed and practised by

M. du Trembley twenty-five years ago, the ether would be vaporised, and we should be able to start afresh with high tension vapour, which in its turn would be expanded until the frictional limit was again reached. At that point the ether would have to be condensed by the outward application of cold water and pumped back, in the liquid state, to act over again in a similar manner. This method of working was extensively tried in France when introduced by M. du Trembley, and the results were sufficiently encouraging to justify a resumption of the trials at the present time, when they could be made under much more favourable conditions. There was no question as to the economy effected, but in the discussions which took place on the subject it was contended that equally good results might be attained by improved applications of the steam, without resorting to an additional medium. The compound engine of the present day does in fact equal the efficiency of Du Trembley's combined steam- and ether-engine, but there is no reason why the ether apparatus should not confer the same advantage on the modern engine that attended its application to the older form. The objections to its use are purely of a practical nature, and might very possibly yield to persevering efforts at removal.

I need scarcely notice the advantage to be derived from increasing the initial pressure of the steam so as to widen the range of expansion by raising the upper limit of temperature instead of reducing the lower one. It must be remembered however that an increase of temperature is attended with the serious drawback of increasing the quantity of heat carried off by the gases from the fire, and also the loss by radiation, so that we have not so much to gain by increase of pressure as is commonly imagined.

But even supposing the steam-engine to be improved to the utmost extent that practical considerations give us reason to hope for, we should still have to adjudge it a wasteful though a valuable servant. Nor does there appear to be any prospect of substituting with advantage any other form of thermodynamic engine, and thus we are led to inquire whether any other kind of energy is likely to serve us better than heat, for motive power.

Most people, especially those who are least competent to judge, look to electricity as the coming panacea for all mechanical deficiency, and certainly the astonishing progress of electricity as applied to telegraphy, and to those marvellous instruments of recent invention which the British Post Office claims to include in its monopoly of the electric telegraph, as well as the wonderful advance which electricity has made as an illuminating agent, does tend to impress us with faith in its future greatness in the realm of motive power as well.

The difference between heat and electricity in their modes of mechanical action is very wide. Heat acts by expansion of volume which we know to be a necessarily wasteful principle, while electricity operates by attraction and repulsion, and thus produces motion in a manner which is subject to no greater loss of effect than attends the motive action of gravity as exemplified in the ponderable application of falling water in hydraulic machines. If then we could produce electricity with the same facility and economy as heat, the gain would be enormous, but this, as yet at least, we cannot do. At present by far the cheapest method of generating electricity is by the dynamic process. Instead of beginning with electricity to produce power, we begin with power to produce electricity. As a secondary motor an electric engine may, and assuredly will, play an important part in future applications of power, but our present inquiry relates to a primary, and not a secondary, employment of electricity. Thus we are brought to the question, From what source, other than mechanical action, can we hope to obtain a supply of electricity sufficiently cheap and abundant to enable it to take the place of heat as a motive energy? It is commonly said that we know so little of the nature of electricity that it is impossible to set bounds to the means of obtaining it; but ignorance is at least as liable to mislead in the direction of exaggerated expectation as in that of incredulity. It may be freely admitted that the nature of electricity is much less understood than that of heat, but we know that the two are very nearly allied. The doctrine that heat consists of internal motion of molecules may be accepted with almost absolute certainty of its truth. The old idea of heat being a separate entity is no longer held except by those who prefer the fallacious evidence of their senses to the demonstrations of science. So also the old idea of electricity having a separate existence from tangible matter must be discarded, and we are justified in concluding that it is merely a strained or tensional condition of the molecules of matter. Although electricity is more prone to pass into heat than heat into electricity, yet we know that they are mutually convertible. In short I need scarcely remind you, that according to that magnificent generalisation of modern times, so pregnant with great consequences, and for which we are indebted to many illustrious investigators, we now know that heat, electricity, and mechanical action, are all equivalent and transposable forms of energy, of which motion is the essence.

To take a cursory view of our available sources of energy, we have, firstly, the direct heating power of the sun's rays, which as yet we have not succeeded in applying to motive purposes. Secondly we have water power, wind power, and tidal power, all depending upon influences lying outside of our planet. And thirdly we have chemical attraction or affinity. Beyond these there is nothing worth naming. Of the radiant heat of the sun I shall have to speak hereafter, and bearing in mind that we are in search of electricity as a cause, and not an effect, of motive power we may pass over the dynamical agencies comprised under the second head, and direct our attention to chemical affinity as the sole remaining source of energy available for our purpose. At present we derive motive power from chemical attraction through the medium of heat only, and the question is, can we with advantage draw upon the same source through the medium of electricity. The process by which we obtain our supply of heat from the exercise of affinity is that of combustion, in which the substances used consist, on the one hand, of those we call fuel, of which coal is the most important, and on the other, of oxygen, which we derive from the atmosphere. The oxygen has an immense advantage over every other available substance in being omnipresent and costless. The only money value involved is that of the fuel, and in using coal we employ the cheapest oxidisable substance to be found in nature. Moreover the weight of coal used in the combination is only about one-third of the weight of oxygen, so that we only pay upon one-fourth of the whole material consumed. Thus we have conditions of the most favourable description for the production of energy, in the form of heat, and if we could only use the affinities of the same substances with equal facility to evolve electric energy instead of heat energy, there would be nothing more to desire; but as yet there is no appearance of our being able to do this. According to our present practice we consume zinc, instead of coal, in the volaic production of electricity, and not only is zinc thirty or forty times dearer than coal, but it requires to be used in about six-fold larger quantity in order to develop an equal amount of energy. Some people are bold enough to say that with our present imperfect knowledge of electricity we have no right to condemn all plentiful substances, other than coal, as impracticable substitutes for metallic zinc, but it is manifest that we cannot get energy from affinity, where affinity has already been satisfied. The numerous bodies which constitute the mass of our globe, and which we call earths, are bodies in this inert condition. They have already, by the union of the two elements composing them, evolved the energy due to combination, and that energy has ages ago been dissipated in space in the form of heat, never again to be available to us. As well might we try to make fire with ashes, as to use such bodies over again as sources of either heat or electricity. To make them fit for our purpose we should first have to annul their state of combination, and this would require the expenditure of more energy upon them than we could derive from their recombination. Water, being oxidised hydrogen, must be placed in the same category as the earths. In short the only abundant substances in nature possessing strong unsatisfied affinities are those of organic origin, and in the absence of coal, which is the accumulated product of a past vegetation, our supply of such substances would be insignificant. This being the case, until a means be found of making the combination of coal with oxygen directly available for the development of electric energy, as it now is of heat energy, there seems to be no probability of our obtaining electricity from chemical action at such a cost as to supplant heat as a motive agent.

But while still looking to heat as the fountain-head of our power, we may very possibly learn to transmute it, economically, into the more available form of electricity. One method of transformation we already possess, and we have every reason to believe there are others yet to be discovered. We know that when dissimilar metals are joined at opposite ends, and heated at one set of junctions while they are cooled at the other, part of the heat applied disappears in the process, and assumes the form of an electric current. Each couple of metals may be treated as

the cell of a voltaic battery, and we may multiply them to any extent, and group them in series or in parallels, with the same results as are obtained by similar combinations of voltaic cells. The electricity so produced we term Thermo-electricity, and the apparatus by which the current is evolved is the thermo-electric battery. At present this apparatus is even more wasteful of heat than the steam-engine, but considering the very recent origin of this branch of electrical science, and our extremely imperfect knowledge of the actions involved, we may reasonably regard the present thermo-electric battery as the infant condition of a discovery, which, if it follow the rule of all previous discoveries in electricity, only requires time to develop into great practical importance. Now if we possessed an efficient apparatus of this description we could at once apply it to the steam-engine for the purpose of converting into electric energy the heat which now escapes with the rejected steam, and the gases from the fire. The vice of the steam-engine lies in its inability to utilise heat of comparatively low grade, but if we could use up the leavings of the steam-engine by a supplemental machine acting on thermo-electric principles, the present excessive waste would be avoided. We may even anticipate that in the distant future a thermo-electric engine may not only be used as an auxiliary, but in complete substitution of the steam-engine. Such an expectation certainly seems to be countenanced by what we may observe in animated nature. An animal is a living machine dependent upon food both for its formation and its action. That portion of the food which is not used for growth or structural repair, acts strictly as fuel in the production of heat. Part of that heat goes to the maintenance of the animal temperature, and the remainder gives rise to mechanical action. The only analogy between the steam-engine and this living engine is that both are dependent upon the combustion of fuel, the combustion in the one case being extremely slow, and in the other very rapid. In the steam-engine the motion is produced by pressure, but in the animal machine it is effected by muscular contraction. The energy which causes that contraction, if not purely electrical, is so much of that nature that we can produce the same effect by electricity. The conductive system of the nerves is also in harmony with our conception of an electrical arrangement. In fact a description of the animal machine so closely coincides with that of an electrodynamic machine actuated by thermo-electricity, that we may conceive them to be substantially the same thing. At all events, the animal process begins with combustion and ends with electrical action, or something so nearly allied to it as to differ only in kind. And now observe how superior the result is in nature's engine to what it is in ours. Nature only uses heat of low grade, such as we find wholly unavailable. We reject our steam, as useless, at a temperature that would cook the animal substance, while nature works with a heat so mild as not to hurt the most delicate tissue. And yet, notwithstanding the greater availability of high-grade temperature, the quantity of work performed by the living engine relatively to the fuel consumed, puts the steam-engine to shame. How all this is done in the animal organisation we do not yet understand, but the result points to the attainability of an efficient means of converting low-grade heat into electricity, and in striving after a method of accomplishing that object we shall do well to study nature, and profit by the excellence which is there displayed.

But it is not alone in connection with a better utilisation of the heat of combustion that thermo-electricity bears so important an aspect, for it is only the want of an efficient apparatus for converting heat into electricity, that prevents our using the direct heating action of the sun's rays for motive power. In our climate, it is true, we shall never be able to depend upon sunshine for power, nor need we repine on that account so long as we have the preserved sunbeams which we possess in the condensed and portable form of coal, but in regions more favoured with sun and less provided with coal the case would be different. The actual power of the sun's rays is enormous, being computed to be equal to melting a crust of ice 103 feet thick over the whole earth in a year. Within the tropics it would be a great deal more, but a large deduction would everywhere have to be made for absorption of heat by the atmosphere. Taking all things into account, however, we shall not be far from the truth in assuming the solar heat, in that part of the world, to be capable of melting annually, at the surface of the ground, a layer of ice 85 feet thick. Now let us see what this means in mechanical effect. To melt 1 lb. of ice requires 142·4 English units of heat, which, multiplied by 772, gives us 109,932 foot pounds as the mechanical equivalent of the heat consumed in melting a pound of ice. Hence we find that the solar heat, operating upon an area of one acre, in the tropics, and competent to melt a layer of ice 85 feet thick in a year, would, if fully utilised, exert the amazing power of 4000 horses acting for nearly nine hours every day. In dealing with the sun's energy we could afford to be wasteful. Waste of coal means waste of money and premature exhaustion of coal-beds. But the sun's heat is poured upon the earth in endless profusion—endless at all events in a practical sense, for whatever anxiety we may feel as to the duration of coal, we need have none as to the duration of the sun. We have therefore only to consider whether we can divert to our use so much of the sun's motive energy as will repay the cost of the necessary apparatus, and whenever such an apparatus is forthcoming we may expect to bring into subjection a very considerable proportion of the 4000 invisible horses which science tells us are to be found within every acre of tropical ground.

But whatever may be the future of electricity as a prime mover, either in a dominant or subordinate relation to heat, it is certain to be largely used for mechanical purposes in a secondary capacity, that is to say, as the offspring instead of the parent of motive power. The most distinctive characteristic of electricity is that which we express by the word "current," and this gives it great value in cases where power is required in a transmissible form. The term may be objected to as implying a motion of translation analogous to the flow of a liquid through a pipe, whereas the passage of electricity through a conductor must be regarded as a wave-like action communicated from particle to particle. In the case of a fluid current through a pipe, the resistance to the flow increases as the square of the velocity, while in the case of an electric current the resistance through a given conductor is a constant proportion of the energy transmitted. So far therefore as resistance is concerned electricity has a great advantage over water for the transmission of power. The cost of the conductor will however be a grave consideration where the length is great, because its section must be increased in proportion to the length to keep the resistance the same. It must also be large enough in section to prevent heating, which not only represents loss but impairs conductivity. To work advantageously on this system, a high electromotive force must be used, and this will involve loss by imperfect insulation, increasing in amount with the length of the line. For these reasons there will be a limit to the distance to which electricity may be profitably conveyed, but within that limit there will be wide scope for its employment transmissively. Whenever the time arrives for utilising the power of great waterfalls the transmission of power by electricity will become a system of vast importance. Even now small streams of water inconveniently situated for direct application may, by the adoption of this principle, be brought into useful operation.

For locomotive purposes also we find the dynamo-electric principle to be available, as instanced in the very interesting example presented in Siemens' electric railway, which has already attained that degree of success which generally foreshadows an important future. It forms a combined fixed engine and locomotive system of traction, the fixed engine being the generator of the power and the electric engine representing the locomotive.

Steam power may both be transmitted and distributed, by the intervention of electricity, but it will labour under great disadvantage when thus applied, until a thoroughly effective electric accumulator be provided, capable of giving out electric energy with almost unlimited rapidity. How far the secondary battery of M. Faure will fulfil the necessary conditions remains to be seen, and it is to be hoped that the discussions which may be expected to take place at this meeting of the British Association will enable a just estimate of its capabilities to be formed. The introduction of the Faure battery is at any rate a very important step in electrical progress. It will enable motors of small power, whatever their nature may be, to accomplish, by uninterrupted action, the effect of much larger machines acting for short periods, and by this means the value of very small streams of water will be greatly enhanced. This will be especially the case where the power of the stream is required for electric lighting, which, in summer, when the springs are low, will only be required during the brief hours of darkness, while in winter the longer nights will be met by a more abundant supply of water. Even the fitful power of wind, now so little used, will probably acquire new life when aided by a system which will not only collect, but equalise, the variable and uncertain power exerted by the air.

It would greatly add to the utility of the Faure battery if its weight and size could be considerably reduced, for in that case it might be applicable to many purposes of locomotion. We may easily conceive its becoming available in a lighter form for all sorts of carriages on common roads, thereby saving to a vast extent the labour of horses. Even the nobler animal that strides a bicycle, or the one of fainter courage that prefers the safer seat of a tricycle, may ere long be spared the labour of propulsion, and the time may not be distant when an electric horse, far more amenable to discipline than the living one, may be added to the bounteous gifts which science has bestowed on civilised man.

In conclusion I may observe that we can scarcely sufficiently admire the profound investigations which have revealed to us the strict dynamical relation of heat and electricity to outward mechanical motion. It would be a delicate task to apportion praise amongst those whose labours have contributed, in various degrees, to our present knowledge; but I shall do no injustice in saying that of those who have expounded the modern doctrine of energy, in special relation to mechanical practice, the names of Joule, Clausius, Rankine, and William Thomson, will always be conspicuous. But up to this time our knowledge of energy is almost confined to its inorganic aspect. Of its physiological action we remain in deep ignorance, and as we may expect to derive much valuable guidance from a knowledge of Nature's methods of dealing with energy in her wondrous mechanisms, it is to be hoped that future research will be directed to the elucidation of that branch of science which as yet has not even a name, but which I may provisionally term "Animal Energetics."

THE RISE AND PROGRESS OF PALÆONTOLOGY[1]

THAT application of the sciences of biology and geology which is commonly known as palæontology took its origin in the mind of the first person who, finding something like a shell or a bone naturally imbedded in gravel or in rock, indulged in speculations upon the nature of this thing which he had dug out—this "fossil"—and upon the causes which had brought it into such a position. In this rudimentary form, a high antiquity may safely be ascribed to palæontology, inasmuch as we know that, 500 years before the Christian era, the philosophic doctrines of Xenophanes were influenced by his observations upon the fossil remains exposed in the quarries of Syracuse. From this time forth, not only the philosophers, but the poets, the historians, the geographers of antiquity occasionally refer to fossils; and after the revival of learning lively controversies arose respecting their real nature. But hardly more than two centuries have elapsed since this fundamental problem was first exhaustively treated; it was only in the last century that the archæological value of fossils—their importance, I mean, as records of the history of the earth—was fully recognised; the first adequate investigation of the fossil remains of any large group of vertebrated animals is to be found in Cuvier's "Recherches sur les Ossemens Fossiles," completed in 1822; and, so modern is stratigraphical palæontology, that its founder, William Smith, lived to receive the just recognition of his services by the award of the first Wollaston Medal in 1831.

But, although palæontology is a comparatively youthful scientific speciality, the mass of materials with which it has to deal is already prodigious. In the last fifty years the number of known fossil remains of invertebrated animals has been trebled or quadrupled. The work of interpretation of vertebrate fossils, the foundations of which were so solidly laid by Cuvier, was carried on, with wonderful vigour and success, by Agassiz, in Switzerland, by Von Meyer, in Germany, and last, but not least, by Owen in this country, while, in later years, a multitude of workers have laboured in the same field. In many groups of the animal kingdom the number of fossil forms already known is as great as that of the existing species. In some cases it is much greater; and there are entire orders of animals of the existence of which we should know nothing except for the evidence afforded by fossil remains. With all this it may be safely assumed that, at the present moment, we are not acquainted with a tithe of the fossils which will sooner or later be discovered. If we may judge by the profusion yielded within the last few years by the Tertiary formations of North America, there seems to be no limit to the multitude of Mammalian remains to be expected from that continent, and analogy leads us to expect similar riches in Eastern Asia whenever the Tertiary formations of that region are as carefully explored. Again, we have as yet almost everything to learn respecting the terrestrial population of the Mesozoic epoch—and it seems as if the Western Territories of the United States were about to prove as instructive in regard to this point as they have in respect of Tertiary life. My friend Prof. Marsh informs me that, within two years, remains of more than 160 distinct individuals of mammals, belonging to twenty species and nine genera, have been found in a space not larger than the floor of a good-sized room; while beds of the same age have yielded 300 reptiles, varying in size from a length of 60 feet or 80 feet to the dimensions of a rabbit.

The task which I have set myself to-night is to endeavour to lay before you, as briefly as possible, a sketch of the successive steps by which our present knowledge of the facts of palæontology and of those conclusions from them which are indisputable has been attained; and I beg leave to remind you, at the outset, that in attempting to sketch the progress of a branch of knowledge to which innumerable labours have contributed, my business is rather with generalisations than with details. It is my object to mark the epochs of palæontology, not to recount all the events of its history.

That which I just now called the fundamental problem of palæontology, the question which has to be settled before any other can be profitably discussed, is this,—What is the nature of fossils? Are they, as the healthy common sense of the ancient Greeks appears to have led them to assume without hesitation, the remains of animals and plants? Or are they, as was so generally maintained in the fifteenth, sixteenth, and seventeenth centuries, mere figured stones, portions of mineral matter which have assumed the forms of leaves and shells and bones, just as those portions of mineral matter which we call crystals take on the form of regular geometrical solids? Or, again, are they, as others thought, the products of the germs of animals and of the seeds of plants which have lost their way, as it were, in the bowels of the earth, and have achieved only an imperfect and abortive development? It is easy to sneer at our ancestors for being disposed to reject the first in favour of one or other of the last two hypotheses; but it is much more profitable to try to discover why they, who were really not one whit less sensible persons than our excellent selves, should have been led to entertain views which strike us as absurd. The belief in what is erroneously called spontaneous generation—that is to say, in the development of living matter out of mineral matter, apart from the agency of pre-existing living matter, as an ordinary occurrence at the present day—which is still held by some of us, was universally accepted as an obvious truth by them. They could point to the arborescent forms assumed by hoar-frost and by sundry metallic minerals as evidence of the existence in nature of a "plastic force" competent to enable inorganic matter to assume the form of organised bodies. Then, as every one who is familiar with fossils knows, they present innumerable gradations, from shells and bones which exactly resemble the recent objects, to masses of mere stone which, however accurately they repeat the outward form of the organic body, have nothing else in common with it; and, thence, to mere traces and faint impressions in the continuous substance of the rock. What we now know to be the results of the chemical changes which take place in the course of fossilization, by which mineral is substituted for organic substance, might, in the absence of such knowledge, be fairly interpreted as the expression of a process of development in the opposite direction—from the mineral to the organic. Moreover, in an age when it would have seemed the most absurd of paradoxes to suggest that the general level of the sea is constant, while that of the solid land fluctuates up and down through thousands of feet in a secular ground swell, it may well have appeared far less hazardous to conceive that fossils are sports of nature than to accept the necessary alternative, that all the inland regions and highlands, in the rocks of which marine shells had been found, had once been covered by the ocean. It is not so surprising, therefore, as it may at first seem, that although such men as Leonardo da Vinci and Bernard Palissy took just views of the nature of fossils, the opinion of the majority of their contemporaries set strongly the other way; nor even that error maintained itself long after the scientific grounds of the true interpretation of fossils had been stated, in a manner that left nothing to be desired, in the latter half of the seventeenth century. The person who rendered this good service to palæontology was Nicholas Steno,

[1] Discourse given at the York meeting of the British Association by Prof. T. H. Huxley, Sec. R. S. Revised by the author.

professor of anatomy in Florence, though a Dane by birth. Collectors of fossils at that day were familiar with certain bodies termed "glossopetræ," and speculation was rife as to their nature. In the first half of the seventeenth century, Fabio Colonna had tried to convince his colleagues of the famous Accademia dei Lincei that the glossopetræ were merely fossil sharks' teeth, but his arguments made no impression. Fifty years later Steno re-opened the question, and, by dissecting the head of a shark and pointing out the very exact correspondence of its teeth with the glossopetræ, left no rational doubt as to the origin of the latter. Thus far, the work of Steno went little further than that of Colonna, but it fortunately occurred to him to think out the whole subject of the interpretation of fossils, and the results of his meditations was the publication, in 1669, of a little treatise with the very quaint title of "De Solido intra Solidum naturaliter contento." The general course of Steno's argument may be stated in a few words. Fossils are solid bodies which by some natural process have come to be contained within other solid bodies—namely, the rocks in which they are imbedded; and the fundamental problem of palæontology, stated generally, is this—"Given a body endowed with a certain shape and produced in accordance with natural laws, to find in that body itself the evidence of the place and manner of its production."[1] The only way of solving this problem is by the application of the axiom that "like effects imply like causes," or as Steno puts it, in reference to this particular case, that "bodies which are altogether similar have been produced in the same way."[2] Hence, since the glossopetræ are altogether similar to sharks' teeth, they must have been produced by shark-like fishes; and since many fossil shells correspond, down to the minutest details of structure, with the shells of existing marine or freshwater animals, they must have been produced by similar animals; and the like reasoning is applied by Steno to the fossil bones of vertebrated animals, whether aquatic or terrestrial. To the obvious objection that many fossils are not altogether similar to their living analogues, differing in substance while agreeing in form, or being mere hollows or impressions, the surfaces of which are figured in the same way as those of animal or vegetable organisms, Steno replies by pointing out the changes which take place in organic remains imbedded in the earth, and how their solid substance may be dissolved away entirely, or replaced by mineral matter, until nothing is left of the original but a cast, an impression, or a mere trace of its contours. The principles of investigation thus excellently stated and illustrated by Steno in 1669, are those which have, consciously, or unconsciously, guided the researches of palæontologists ever since. Even that feat of palæontology which has so powerfully impressed the popular imagination, the reconstruction of an extinct animal from a tooth or a bone, is based upon the simplest imaginable application of the logic of Steno. A moment's consideration will show, in fact, that Steno's conclusion that the glossopetræ are sharks' teeth implies the reconstruction of an animal from its tooth. It is equivalent to the assertion that the animal of which the glossopetræ are relics had the form and organisation of a shark; that it had a skull, a vertebral column, and limbs similar to those which are characteristic of this group of fishes; that its heart, gills, and intestines presented the peculiarities which those of all sharks exhibit; nay, even that any hard parts which its integument contained were of a totally different character from the scales of ordinary fishes. These conclusions are as certain as any based upon probable reasonings can be. And they are so, simply because a very large experience justifies us in believing that teeth of this particular form and structure are invariably associated with the peculiar organisation of sharks, and are never found in connection with other organisms. Why this should be we are not at present in a position even to imagine; we must take the fact as an empirical law of animal morphology, the reason of which may possibly be one day found in the history of the evolution of the shark tribe, but for which it is hopeless to seek for an explanation in ordinary physiological reasonings. Every one practically acquainted with palæontology is aware that it is not every tooth nor every bone which enables us to form a judgment of the character of the animal to which it belonged, and that it is possible to possess many teeth, and even a large portion of the skeleton of an extinct animal, and yet be unable to reconstruct its skull or its limbs. It is only when the tooth or bone presents peculiarities which we know by previous experience to be characteristic of a certain group that we can safely predict that the fossil belonged to an animal of the same group. Any one who finds a cow's grinder may be perfectly sure that it belonged to an animal which had two complete toes on each foot, and ruminated; any one who finds a horse's grinder may be as sure that it had one complete toe on each foot and did not ruminate; but, if ruminants and horses were extinct animals of which nothing but the grinders had ever been discovered, no amount of physiological reasoning could have enabled us to reconstruct either animal, still less to have divined the wide differences between the two. Cuvier, in the "Discours sur les Révolutions de la Surface du Globe," strangely credits himself, and has ever since been credited by others, with the invention of a new method of palæontological research. But if you will turn to the "Recherches sur les Ossemens Fossiles" and watch Cuvier, not speculating, but working, you will find that his method is neither more nor less than that of Steno. If he was able to make his famous prophecy from the jaw which lay upon the surface of a block of stone to the pelvis of the same animal which lay hidden in it, it was not because either he, or any one else, knew, or knows, why a certain form of jaw is, as a rule, constantly accompanied by the presence of marsupial bones—but simply because experience has shown that these two structures are co-ordinated.

The settlement of the nature of fossils led at once to the next advance of palæontology—viz., its application to the deciphering of the history of the earth. When it was admitted that fossils are remains of animals and plants, it followed that, in so far as they resemble terrestrial or freshwater animals and plants, they are evidences of the existence of land or fresh water, and in so far as they resemble marine organisms, they are evidences of the existence of the sea at the time at which they were parts of actually living animals and plants. Moreover, in the absence of evidence to the contrary, it must be admitted that the terrestrial or the marine organisms implied the existence of land or sea at the place in which they were found while they were ye living. In fact, such conclusions were immediately drawn by everybody, from the time of Xenophanes downwards, who believed that fossils were really organic remains. Steno discusses their value as evidence of repeated alteration of marine and terrestrial conditions upon the soil of Tuscany in a manner worthy of a modern geologist. The speculations of De Maillet in the beginning of the eighteenth century turn upon fossils, and Buffon follows him very closely in those two remarkable works, the "Théorie de la Terre" and the "Époques de la Nature," with which he commenced and ended his career as a naturalist.

The opening sentences of the "Époques de la Nature" show us how fully Buffon recognised the analogy of geological with archæological inquiries. "As in civil history we consult deeds, seek for coins, or decipher antique inscriptions in order to determine the epochs of human revolutions and fix the date of moral events; so, in natural history, we must search the archives of the world, recover old monuments from the bowels of the earth, collect their fragmentary remains, and gather into one body of evidence all the signs of physical change which may enable us to look back upon the different ages of nature. It is our only means of fixing some points in the immensity of space and of setting a certain number of waymarks along the eternal path of time."

Buffon enumerates five classes of these monuments of the past history of the earth, and they are all facts of palæontology. In the first place, he says, shells and other marine productions are found all over the surface and in the interior of the dry land; and all calcareous rocks are made up of their remains. Secondly, a great many of these shells which are found in Europe are not now to be met with in the adjacent seas; and, in the slates and other deep-seated deposits, there are remains of fishes and of plants of which no species now exist in our latitudes, and which are either extinct or exist only in more northern climates. Thirdly, in Siberia and in other northern regions of Europe and of Asia, bones and teeth of elephants, rhinoceroses, and hippopotamuses occur in such numbers that these animals must once have lived and multiplied in those regions, although at the present day they are confined to southern climates. The deposits in which these remains are found are superficial, while those which contain shells and other marine remains lie much deeper. Fourthly, tusks and bones of elephants and hippopotamuses are found not only in the northern regions of the

[1] "De Solido intra Solidum," p 5.—"Dato corpore certâ figurâ prædito et juxta leges naturæ producto, in ipso corpore argumenta invenire locum et modum productionis detegentia."

[2] "Corpora sibi invicem omnino similia simili etiam modo producta sunt."

old world, but also in those of the new world, although, at present, neither elephants nor hippopotamuses occur in America. Fifthly, in the middle of the continents, in regions most remote from the sea, we find an infinite number of shells, of which the most part belong to animals of those kinds which still exist in southern seas, but of which many others have no living analogues; so that these species appear to be lost, destroyed by some unknown cause. It is needless to inquire how far these statements are strictly accurate; they are sufficiently so to justify Buffon's conclusions that the dry land was once beneath the sea; that the formation of the fossiliferous rocks must have occupied a vastly greater lapse of time than that traditionally ascribed to the age of the earth; that fossil remains indicate different climatal conditions to have obtained in former times, and especially that the polar regions were once warmer; that many species of animals and plants have become extinct; and that geological change has had something to do with geographical distribution.

But these propositions almost constitute the framework of palæontology. In order to complete it but one addition was needed, and that was made, in the last years of the eighteenth century, by William Smith, whose work comes so near our own times that many living men may have been personally acquainted with him. This modest land surveyor, whose business took him into many parts of England, profited by the peculiarly favourable conditions offered by the arrangement of our secondary strata to make a careful examination and comparison of their fossil contents at different points of the large area over which they extend. The result of his accurate and widely-extended observations was to establish the important truth that each stratum contained certain fossils which are peculiar to it; and that the order in which the strata, characterised by these fossils, are superimposed one upon the other is always the same. This most important generalisation was rapidly verified and extended to all parts of the world accessible to geologists; and, now, it rests upon such an immense mass of observations as to be one of the best established truths of natural science. To the geologist this discovery was of infinite importance, as it enabled him to identify rocks of the same relative age, however their continuity might be interrupted or their composition altered. But to the biologist it had a still deeper meaning, for it demonstrated that, throughout the prodigious duration of time registered by the fossiliferous rocks, the living population of the earth had undergone continual changes, not merely by the extinction of a certain number of the species which at first existed, but by the continual generation of new species, and the no less constant extinction of old ones.

Thus, the broad outlines of palæontology, in so far as it is the common property of both the geologist and the biologist, were marked out at the close of the last century. In tracing its subsequent progress I must confine myself to the province of biology, and, indeed, to the influence of palæontology upon zoological morphology. And I accept this limitation the more willingly as the no less important topic of the bearing of geology and of palæontology upon distribution has been luminously treated in the address of the President of the Geographical Section.

The succession of the species of animals and plants in time being established, the first question which the zoologist or the botanist had to ask himself was, What is the relation of these successive species one to another? And it is a curious circumstance that the most important event in the history of palæontology which immediately succeeded William Smith's generalisation was a discovery which, could it have been rightly appreciated at the time, would have gone far towards suggesting the answer, which was in fact delayed for more than half a century. I refer to Cuvier's investigation of the Mammalian fossils yielded by the quarries in the older Tertiary rocks of Montmartre, among the chief results of which was the bringing to light of two genera of extinct hoofed quadrupeds, the *Anoplotherium* and the *Palæotherium*. The rich materials at Cuvier's disposition enabled him to obtain a full knowledge of the osteology and of the dentition of these two forms, and consequently to compare their structure critically with that of existing hoofed animals. The effect of this comparison was to prove that the *Anoplotherium*, though it presented many points of resemblance with the pigs on the one hand, and with the ruminants on the other, differed from both to such an extent that it could find a place in neither group. In fact, it held, in some respects, an intermediate position, tending to bridge over the interval between these two groups, which in the existing fauna are so distinct. In the same way, the *Palæotherium* tended to connect forms so different as the tapir, the rhinoceros, and the horse. Subsequent investigations have brought to light a variety of facts of the same order, the most curious and striking of which are those which prove the existence, in the mesozoic epoch, of a series of forms intermediate between birds and reptiles—two classes of vertebrate animals which at present appear to be more widely separated than any others. Yet the interval between them is completely filled, in the mesozoic fauna, by birds which have reptilian characters on the one side, and reptiles which have ornithic characters, on the other. So, again, while the group of fishes termed ganoids is at the present time so distinct from that of the dipnoi, or mudfishes, that they have been reckoned as distinct orders, the Devonian strata present us with forms of which it is impossible to say with certainty whether they are dipnoi or whether they are ganoids.

Agassiz's long and elaborate researches upon fossil fishes, published between 1833 and 1842, led him to suggest the existence of another kind of relation between ancient and modern forms of life. He observed that the oldest fishes presented many characters which recall the embryonic conditions of existing fishes; and that, not only among fishes, but in several groups of the invertebrata which have a long palæontological history, the latest forms are more modified, more specialised, than the earlier. The fact that the dentition of the older tertiary ungulate and carnivorous mammals is always complete, noticed by Prof. Owen, illustrated the same generalisation.

Another no less suggestive observation was made by Mr. Darwin, whose personal investigations during the voyage of the *Beagle* led him to remark upon the singular fact, that the fauna which immediately precedes that at present existing in any geographical province of distribution presents the same peculiarities as its successor. Thus, in South America and in Australia, the later tertiary or quaternary fossils show that the fauna which immediately preceded that of the present day was, in the one case, as much characterised by edentates and in the other by marsupials as it is now, although the species of the older are largely different from those of the newer fauna.

However clearly these indications might point in one direction, the question of the exact relation of the successive forms of animal and vegetable life could be satisfactorily settled only in one way—namely, by comparing, stage by stage, the series of forms presented by one and the same type throughout a long space of time. Within the last few years this has been done fully in the case of the horse, less completely in the case of the other principal types of the ungulata and of the carnivora, and all these investigations tend to one general result—namely, that in any given series the successive members of that series present a gradually increasing specialisation of structure. That is to say, if any such mammal at present existing has specially modified and reduced limbs or dentition and complicated brain, its predecessors in time show less and less modification and reduction in limbs and teeth and a less highly developed brain. The labours of Gaudry, Marsh, and Cope furnish abundant illustrations of this law from the marvellous fossil wealth of Pikermi and the vast uninterrupted series of tertiary rocks in the territories of North America.

I will now sum up the results of this sketch of the rise and progress of palæontology. The whole fabric of palæontology is based upon two propositions: the first is, that fossils are the remains of animals and plants; and the second is, that the stratified rocks in which they are found are sedimentary deposits; and each of these propositions is founded upon the same axiom that like effects imply like causes. If there is any cause competent to produce a fossil stem, or shell, or bone, except a living being, then palæontology has no foundation; if the stratification of the rocks is not the effect of such causes as at present produce stratification, we have no means of judging of the duration of past time, or of the order in which the forms of life have succeeded one another. But, if these two propositions are granted, there is no escape, as it appears to me, from three very important conclusions. The first is that living matter has existed upon the earth for a vast length of time, certainly for millions of years. The second is that, during this lapse of time, the forms of living matter have undergone repeated changes, the effect of which has been that the animal and vegetable population at any period of the earth's history contains some species which did not exist at some antecedent period, and others which ceased to exist at some subsequent period. The third is that in the case of many groups of mammals and some of reptiles, in which one type can be followed through a considerable extent of geological time, the series of different forms by which the type is represented at successive intervals of this time is exactly such as it would be if

they had been produced by the gradual modification of the earliest form of the series. These are facts of the history of the earth guaranteed by as good evidence as any facts in civil history.

Hitherto I have kept carefully clear of all the hypotheses to which men have at various times endeavoured to fit the facts of palæontology, or by which they have endeavoured to connect as many of these facts as they happened to be acquainted with. I do not think it would be a profitable employment of our time to discuss conceptions which doubtless have had their justification and even their use, but which are now obviously incompatible with the well-ascertained truths of palæontology. At present these truths leave room for only two hypotheses. The first is that, in the course of the history of the earth, innumerable species of animals and plants have come into existence, independently of one another, innumerable times. This, of course, implies either that spontaneous generation on the most astounding scale, and of animals such as horses and elephants, has been going on, as a natural process, through all the time recorded by the fossiliferous rocks; or it necessitates the belief in innumerable acts of creation repeated innumerable times. The other hypothesis is, that the successive species of animals and plants have arisen, the later by the gradual modification of the earlier. This is the hypothesis of evolution; and the palæontological discoveries of the last decade are so completely in accordance with the requirements of this hypothesis that, if it had not existed, the palæontologist would have had to invent it.

I have always had a certain horror of presuming to set a limit upon the possibilities of things. Therefore, I will not venture to say that it is impossible that the multitudinous species of animals and plants may have been produced one separately from the other by spontaneous generation, nor that it is impossible that they should have been independently originated by an endless succession of miraculous creative acts. But I must confess that both these hypotheses strike me as so astoundingly improbable, so devoid of a shred of either scientific or traditional support, that even if there were no other evidence than that of palæontology in its favour, I should feel compelled to adopt the hypothesis of evolution. Happily, the future of palæontology is independent of all hypothetical considerations. Fifty years hence, whoever undertakes to record the progress of palæontology will note the present time as the epoch in which the law of succession of the forms of the higher animals was determined by the observation of palæontological facts. He will point out that, just as Steno and as Cuvier were enabled from their knowledge of the empirical laws of coexistence of the parts of animals to conclude from a part to the whole, so the knowledge of the law of succession of forms empowered their successors to conclude, from one or two terms of such a succession, to the whole series, and thus to divine the existence of forms of life, of which, perhaps, no trace remains, at epochs of inconceivable remoteness in the past.

NOTES

MOST of the foreign Governments have appointed their delegates to the International Congress of Electricians at Paris. Among the German delegates are M. Wiedemann, editor of *Wiedemann's Annalen*, Helmholtz, Du Bois-Reymond, and Weber, who, as we stated in our last issue, has received a medal in commemoration of the fiftieth anniversary of his professoriate in Halle. The name of Weber is the only one among living men which has been inscribed on the walls of the Palais de l'Industrie. The original instrument which Weber invented with Gauss in 1833 is exhibited in the German section. Amongst the names of English men of science who are said to have been delegated by the English Government are those of Sir William Thomson and Dr. Siemens. One, if not the principal, object of the deliberations of the Congress will be the adoption of a universal system of electric and magnetic measures, as advocated by the British Association. The work of the Commission which has been appointed by it will be discussed, and practical suggestions are to be made relating to it. It is supposed that the electrical and magnetic units are to be considered as a sequel to the metric system of weights and measures. Another question will relate to the laying of submarine cables, viz., the establishment of an international codex of signals for telegraphic steamers, and the necessity of adopting rules for parallel or transversal lines, liable to endanger the existing ones. But it does not appear that any allusion is to be made to the neutralisation in war time, although it has been recommended by M. Barthélemy St. Hilaire, the Minister of Foreign Affairs. All the sittings are to be private, to the exclusion of the public and Press, except a few lectures given by some members on selected topics. *Procès-verbaux* are to be written and published by a select body of authorised secretaries.

THE telephonic audition of the Opera at the Paris Electrical Exhibition is very popular. Not less than 1500 people are admitted by relays of twenty-four, during two minutes at a time, to enjoy it every opera night. It was contemplated to transmit the performances from the Théâtre Français on the same principle, but it has not been successful. The receipts of the Exhibition exceed 4000*l.* daily.

A SIXTH electrical paper has been started in Paris. It is a large folio issued every Saturday, and called *Moniteur officiel de l'Électricité*. It is conducted by M. Barbieny, a gentleman connected with the political Press, and who has founded several periodicals. Electricity has now more papers in Paris than general science.

THE will of the late Sir Josiah Mason of Birmingham has just been proved. The personal estate was sworn to be of the value of 56,729*l.* The testator had no real property, having in his lifetime disposed of his real estate, worth upwards of 10,000*l.* per annum, either to his orphanage or college trustees, or his great nephew. After legacies and bequests amounting to 7500*l.*, the whole of the testator's personal estate by law applicable to charitable purposes is bequeathed to the trustees of the Mason Science College, for the general purposes of the institution. Elaborate provisions are made for charging the debts, annuities, and legacies on the property which cannot legally be bequeathed to charitable purposes, so as to secure the whole residue for the college.

DR. ARCHIBALD BILLING, M.A., F.R.S., the author of the "First Principles of Medicine," died in London on Friday, at the age of ninety. The deceased physician, who was a native of Ireland, was born in 1791, and was educated at Trinity College, Dublin, and at Oxford, graduating at the first-named University. While engaged at the London Hospital, he instituted the series of chemical lectures which have since become an established feature of the medical school at that institution, but resigned his appointment at the close of 1836, upon the establishment of the University of London. Dr. Billing was a large contributor to the medical Press. He was a member of a large number of learned societies, both in this country and on the Continent.

A CONVENTION of American photographers has recently concluded its sittings at New York. Before separating the members appointed a committee to consider the feasibility of forming an International Photographic Association, and to confer with foreign societies with that view. A report upon the subject will be presented at the next meeting of the Convention, which is to take place at Indianopolis.

THE American Association for the Advancement of Science, at its meeting last month in Cincinnati, took action in reference to the scandal of American degrees, by resolving to unite with the American Philological Association in presenting a memorial to all colleges in the United States empowered to confer degrees, stating the objections to conferring the degree of Ph.D. *honoris causâ*, and praying them to discontinue the practice, if it exists. It seems that the reprehensible practice has been growing of late in the United States. There are, it would seem, in the United

States, 360 institutions of a collegiate grade; these colleges and universities receive their charters from the Legislature of their several States, these charters giving them the unlimited right to confer degrees. The president of the college near Cincinnati told one of the speakers, with a face shining with pride, that his college gave seventeen different degrees. One of these was M.P., which in interpretation meant, not Member of Parliament, but Master of Penmanship. It would seem, moreover, that even the degree of S.D. (equivalent, we believe, to our D.Sc.) has actually been granted by some of these American institutions *honoris causâ*. We trust that the action of the American Association will have some influence with the peccant colleges; it will, at any rate, put people on their guard against American Ph.D.'s and S.D.'s, as well as D.D.'s.

In the *Revue Scientifique* of September 3, Mr. G. Delaunay has a paper on the "Equality and Inequality of the Two Sexes," in which he endeavours to show that except in some of the lowest forms of animal life, and in the lowest stages of human society, the inferiority of the female sex to the male is unmistakable in all respects—that physically, mentally, and morally, woman is the inferior of man.

A huge mass of rock and earth fell the other day from a mountain side at Somnix in the Grisons, blocked up the course of the Jobel, an affluent of the Rhine, and converted the valley into a lake. The village of Surrheim, hard by, is in great danger.

The additions to the Zoological Society's Gardens during the past week include two Malbrouck Monkeys (*Cercopithecus cynosurus*) from West Africa, presented by Mr. H. P. Sherlock; a Central American Agouti (*Dasyprocta isthmica*) from Central America, presented by Mr. J. E. Sharp; two Spotted Cavys (*Cœlogenys paca*) from South America, presented by Dr. Portella; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. James W. Duncan; two Domestic Pigeons (*Columba œnas*, var.) from Arabia, presented by Mr. Reginald Zohrab; three Common Chamæleons (*Chamæleon vulgaris*) from North Africa, presented by Mr. Alfred R. Rogers; two Greater Sulphur-crested Cockatoos (*Cacatua galerita*) from Australia, deposited; a Black-headed Caique (*Caica melanocephala*) from Demerara, purchased. The additions to the Insectarium for the past week include *Attacus permyi*, second brood of larvæ hatched; also *Attacus cynthia*, imago second brood, and the Death's-Head Moth (*Acherontia atropos*) larva, presented by Master Kingchurch; second brood of Ant Lions (Myrmeleons), and a brood of the Edible Snail (*Helix pomatia*) from specimens presented by Lord A. Russell, F.Z.S., in April last.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 29.—M. Decaisne in the chair.—M. Faye presented the first volume of his "Cours d'Astronomie de l'École Polytechnique," treating of the diurnal motion, the theory of instruments and errors, organisation of great observatories, mathematics and geodesy. The second volume will be devoted to the solar system.—Dioptric studies, by M. Zenger. He constructs tables which give, in algebraic form, the relation between the radii of curvature and refractive indices of two media forming the objective of a microscope or telescope. Any one may make his own telescope or microscope, without calculation, taking a lens of quartz or crown glass, and a mixture of aromatic substances giving it a dispersion twice as great, or equal for all spectral rays. The lens being corrected, it is combined with one or two other symmetrical lenses, according to the well-known process for getting an aplanetic and achromatic doublet or triplet.—MM. Tresca and Breguet were requested to represent the Academy at the inauguration of the monument to Frederic Sauvage in Boulogne on the 12th inst.—On a very old application of the screw as an organ of propulsion, by M. Govi. This was by Leonardo da Vinci, about the end of the fifteenth century. In one of his works is a sketch of a device for rising in the air, consisting of a helix formed of wire and cloth to be rotated about a vertical axis. He seems to have made small paper models actuated by thin slips of steel, twisted, then left to themselves. Another sketch shows that Leonardo da Vinci conceived the idea of the parachute.—On some new cases of equipotential figures, realised electro-chemically, by M. Guébhard.—On the absorption of ultra-violet rays by some media, by M. de Chardonnet. Two methods are described. The liquids which circulate in plants or impregnate roots and fruits show a great avidity for chemical rays. Fluorescence does not appear to be in direct ratio to the intensity of actinic absorption; thus, *e.g.* the decoction of radish is a less powerful absorbent than that of potatoes; yet the former is fluorescent, the latter not. White wine is weakly fluorescent, red wine lacks the property. The few animal substances studied gave very varied results. While blood, even very dilute, is a strong absorbent, the (fresh) aqueous humour of a calf's eye and the albumen of hen's eggs have no action on the chemical rays (at least up to 20 mm. thickness). Distilled water, alcohol, sulphuric ether, normal collodion, and solution of cane-sugar are also without action. Gelatine appropriates readily all the actinic rays. An object-glass of Dallmeyer projected an invisible spectrum 25 to 40 per cent. longer than one of Darlot, of Paris, of equal focus.—Figures produced by fall of a drop of water holding minium in suspension, by M. Decharme. Minium, in fine powder, is mixed with water and spread uniformly on a horizontal glass plate; then a drop of the mixture is let fall on this layer. Figures resembling those of the three systems Caladni observed on vibrating plates are produced; the three types usually coexist, but one or other may be made to predominate at will.—On the composition of buckwheat, by M. Lechartier. Marked differences appear between the crops of 1879 and of 1880. Thus the ashes of the straw in 1880 had twice as much potash as in 1879, and phosphoric acid was still more increased; and there was also more chlorine. The composition of the grain is little modified. The straw may contain more of mineral matter than the grain. Buck-wheat removes more of the fertilising principles from the soil than corn.—On hydrosulphurous acid; reply to M. Schutzenberger's note, by M. Bernthsen.—On the dissolution of silver in presence of alkaline iodides, by M. Ditte.—On the constitution of glyceric ether, and on the transformation of epichlorhydrine into normal propylic alcohol, by M. Silva.—On pyruvic alcohol and its derivatives, by M. Henry.—Action of triethylamine on epichlorhydrine; compounds of oxallyltriethylammonium, by M. Reboul.—Biological evolution of the pucerons of the alder tree, by M. Lichtenstein.—Observations on a new enunciation of the second law of Gay-Lussac concerning combinations of gas, by M. Garcia de la Cruz. He indicates some of the numerous exceptions to M. Verschaffel's proposition: "The space occupied by a gaseous compound is always double the space occupied by that one of the components which enters with less volume into the combination." This law he regards as less general than the laws of contraction long accepted.

THE THEORY OF DESCENT

Studies in the Theory of Descent. By Dr. Aug. Weismann, Professor in the University of Freiburg. Translated and Edited by Raphael Meldola, F.C.S. Part II. On the Origin of the Markings of Caterpillars. On Phyletic Parallelism in Metamorphic Species. With Six Coloured Plates. (London: Sampson Low, Marston, Searle, and Rivington, 1881.)

THE first part of this work, devoted to an examination of the phenomena of seasonal dimorphism in butterflies, was noticed a little more than a year ago (NATURE, vol. xxii. p. 141). We now have a second instalment of much greater bulk, comprising two separate essays. In the first and most important of these Dr. Weismann gives us the results of a detailed study of the changes in the markings of the caterpillars of the Sphingidæ during the course of their growth and development, and enters at great length into the various questions to which the phenomena observed give rise. Accepting the doctrine that the *ontogeny* or development of the individual gives us a more or less accurate notion of the *phylogeny* or course of development of the race, he endeavours with some success to determine the ancestral forms of the various genera of the Sphingidæ by means of the successive changes of form and coloration of the larvæ. The main facts which he has here established are, that all the larvæ are born of a uniform tint—that the first markings are longitudinal lines—that the oblique lines when they exist always appear later, and the ringed or ocellated spots last of all. Great changes of colour also occur in some species, but all the more important changes, whether of colour or marking, only take place after the larvæ have acquired a considerable size. From the whole assemblage of facts in this branch of the inquiry he deduces the following three laws of development:—

"1. The development commences with a state of simplicity, and advances gradually to one of complexity.

"2. New characters first make their appearance in the last stage of the ontogeny.

"3. Such characters then become gradually carried back to the earlier ontogenetic stages, thus displacing the older characters until the latter disappear completely."

These laws are liable to be modified in various ways by the influence of natural selection, and especially by the need for protection, whence arise the various markings of the different groups, and the peculiar divergences often noted in their development at corresponding ages.

Having thus established the general developmental history of the markings of caterpillars, and explained by a few simple principles the chief anomalies they present, Dr. Weismann passes on to the still more interesting inquiry as to the biological value or actual meaning and use of the markings in each individual case. He first shows that colour itself, irrespective of marking, has a distinct biological value, being always either protective or a signal of uneatableness. The Sphinx larvæ when young are almost always green, resembling the leaves of the plants on which they feed and rest. When they get larger, however, they frequently change to brown, and this change is always accompanied by a change in habits, the insect feeding at night, but during the day concealing itself on the ground or amidst dead leaves and branches. This occurs chiefly among the species which feed on low shrubs or herbs and can thus easily descend to the ground to conceal themselves during the day; while those which feed on large trees acquire markings which assimilate them more completely to the foliage or flowers which surround them. The simplest form of marking—longitudinal stripes—is common on all caterpillars which feed on grasses or other plants in which straight *lines* are a prevalent feature, and this style of marking is that which usually appears in the young sphinx larvæ. But as they grow larger diagonal stripes or bands variously tinted or shaded appear, and this style of marking is found to assimilate so well with the oblique veining of the leaves that the caterpillars are very difficult to see when resting among them. This is the case even when the oblique lines are margined with violet or other bright colours, since, however conspicuous these markings may be when the insect is examined in captivity, they are found to blend perfectly with the lights and shadows of the foliage which surround it in its natural habitat. As an example we have the following account of the brilliantly coloured larva of the Death's-Head Moth on one of its natural food-plants:—

"At Cadiz on the hot, sandy shore, *Solanum violaceum* grows to the height of three feet, and on a single plant I often found more than a dozen *Atropos* larvæ resting with the head retracted. It can easily be understood why the lateral stripes are blue when one has seen the South European *Solaneæ*, on which this larva is at home. *Solanum violaceum* is scarcely green: violet tints alternate with brown, green, and yellow over the whole plant, and between these appear the yellow-anthered flowers, and golden yellow berries the size of a greengage. Thus it happens that the numerous thorns, an inch long, between which the caterpillar rests on the stem, pass from violet into shades of blue, red, green, and yellow."

Many of the adult sphinx larvæ however are adorned with ring-spots or eye-spots, and these have been found to serve two distinct purposes. Sometimes they occur on several of the segments, but of slightly different sizes, as in a North American species (*Chærocampa tersa*), the red spots on which imitate the small red flowers of the plant on which it feeds; while in the European *Deilephila hippophaes*, the grey-green larva with orange-red spots so exactly assimilates to the foliage and fruit of the sea-buckthorn on which it feeds, that Dr. Weismann has often shown to people as many as six or eight of the large caterpillars on one buckthorn branch without their being able at once to detect them. In other cases we find very large eye-spots on the fourth or fifth segments only, coupled with the habit of retracting the head and first three segments, so that an appearance is produced of a broad head with two very conspicuous eyes. Whenever the insect is disturbed it thus retracts itself, and it has often been conjectured that the effect is to frighten away its enemies. This Dr. Weismann has proved to be actually the case. On placing the larva of the Elephant Hawk-Moth (*Chærocampa Elpenor*) in a trough used for feeding fowls, a number of sparrows and chaffinches flew down from the neighbouring trees to pick up some stray food.

"One bird soon flew on to the edge of the trough, and

was just about to hop into it when it caught sight of the caterpillar, and stood jerking its head from side to side, but did not venture to enter. Another bird soon came, and behaved in a precisely similar manner; then a third, and a fourth; others settled on the perch over the trough, and a flock of ten or twelve were finally perched around. They all stretched their heads and looked into the trough, but none flew into it."

On removing the caterpillar the birds again assembled, and at once entered the trough to feed. Fowls were also frightened at first, and would draw back just as they were going to peck at the caterpillar. At last, after several had tried, and even made ineffectual attempts to peck, one more courageous than the rest would actually touch it, and after a time, finding nothing disagreeable, the insect would be swallowed. In the genus Deilephila, however, there are uneatable caterpillars, and these have strongly contrasted black and white or yellow spots combined with the habit of fully exposing themselves upon their food plants. Dr. Weismann experimented with two species (*D. galii* and *D. euphorbiæ*) and found that they were refused by birds, though the latter was eaten by lizards. It is to be noted however that the experiments were made with a South European species of lizard, not that of Germany, so that the result has not a direct bearing on the point.

The general conclusion at which Dr. Weismann arrives is, that all the varieties of colour and marking occurring in the Sphingidæ have a distinct biological value, and can in every case be traced to the action of natural selection and correlation of growth.

The next essay is not quite so interesting or important. It is an endeavour to prove, by a distinct line of inquiry, that the markings of the larvæ are not due to a "phyletic vital force" or to general laws of growth and development. The different groups of Sphingidæ are minutely examined and compared in their three stages of larva, pupa, and imago, and it is shown that the changes that occur from species to species in each stage are to a great extent independent of the changes in the other stages. Numerous examples of this want of phyletic parallelism are given, and it is hence argued that the modifications which occur must be due to an adaptation to the special conditions to which the insect is exposed in one or other of its states, not to any innate law of variation and development, which, it is argued, would affect all the stages *pari passu* and produce a "phyletic parallelism" which does not actually exist. The same general facts are shown to prevail, not only among Lepidoptera generally, but among all insects and crustacea—or generally among all organisms which undergo a metamorphosis.

This instalment of the work has been admirably translated and edited by Mr. Meldola, who, in a series of valuable notes and an Appendix, has brought up the information on every branch of the inquiry to the latest date. The six coloured plates of larvæ in their several stages are very well executed, and serve to illustrate the somewhat complex discussion in a clear and effective manner.

ALFRED R. WALLACE

OUR BOOK SHELF

The Wandering Jew. By Moncure Daniel Conway. (London: Chatto and Windus, 1881.)

THIS last volume of Mr. Conway's is a study, not only of the legend of the Wandering Jew, but with it of the large group of analogous myths of undying men who from age to age wander over the earth, or sleep in caverns, or are translated from among men into divine regions, whence however they come back and show themselves still living men. The interest of these stories in the history of philosophy lies in their keeping up men's early ideas of life and death. One of Mr. Conway's purposes in discussing them is to draw attention to their being relics of the primitive period when men were still so far from definitely realising the nature of death, that they had no difficulty in regarding kings, heroes, and prophets as having only departed for a while from among them, to return in a future age to rule and protect their expectant nations. In comparative mythology this group of stories has some importance. They show the beliefs of various races running curiously into one another, as where the Lancashire peasant still hears in the cry of the plover the wail of the Wandering Jew, or in the Harz Mountains his myth has got mixed with that of a grander wanderer, the Wild Huntsman, who courses with his storm-clouds across the sky. The storm-demon whom mythic fancy imagines rushing through the air is often called a *Maccabee*, and Mr. Conway points out why he has this name. It is because of a verse in the Second Book of Maccabees, chap. v., which, by the way, is a good instance of the personal forms taken by the fancy of an excited people: "And then it happened, that through all the city, for the space almost of forty days, there were seen horsemen running in the air, in cloth of gold, and armed with lances, like a band of soldiers." Unfortunately some other etymologies made or quoted by Mr. Conway are not so reasonable as this. When the names of biblical personages, *Herod* and *Ahasuerus*, find their way into European myths, it may not be easy to explain how they got there, but at any rate it is better to leave them alone than to make up imaginary and even impossible German or Scandinavian forms, *Haar-Rote*, *As-Vidar*, to account for their presence. It would be easy to take exception to many of the arguments in this volume, but at any rate there are many interesting points in it.

A Short Sketch of the Geology of Yorkshire. By Charles Bird, B.A. (Univ. Lond.) (London: Simpkin, Marshall, and Co.; Bradford: Thomas Brear, 1881; pp. 187 and Map.)

Geological Map of Yorkshire. By the same Author. (Edinburgh and London: W. and A. K. Johnston; Bradford: T. Brear, 1881.)

IN the preface of this book, written by way of dedication, it is represented to be a "small and cheap volume suitable to the 'general reader' and tourist." It is impossible to say that it is not a useful and interesting one. So much good work has been done on the county, though scattered through very various publications, that a short *résumé* cannot fail to be of value; but there are books and books, and if we measure this by what it might have been, it is poor indeed. It resembles, in fact, geologically speaking, a kind of boulder clay, full of fragments of solid rock, brought from a distance—we will not say to be deposited in mud—but certainly scratched and rubbed in the process. In the beginning of the volume is a list of the surrounding mountains whence the boulders have been derived, but it is not a complete one; and the source of each fragment is not indicated in the body of the text. Its great defect is that it is unstratified; in other words, the extracts are not duly digested, but thrown together without sorting, and with very little alteration; so little indeed that it would not be difficult to trace them to their sources. Thus under the head of "The Carboniferous Period" we have a brief explanation, from a popular lecture, "how from the general mineral character of a rock the circumstances under which it was formed can often be predicated." Then under the head of "Salt water deposits" we have twelve pages on the origin and contents of the Victoria

Cave, which ought surely to belong to the chapter on the "Recent Geological History of Yorkshire," only that the latter happened to be written by one who confined himself to the Holderness drift. Under the head of "The Permian Rocks" there is an exposition of the views of those who would reintroduce the old (not recently suggested) name Poikilitic to include the Trias. It was a pity the author was not acquainted with any recent papers on the series above the Lias, for there are no good boulders in this part of the book. Mr. Hudleston's admirable papers on the Yorkshire Oolites seem to have been written in vain, and there have been modern papers also on the Yorkshire Chalk. It was perhaps excusable for our author to conclude that the third edition of Prof. Phillips' "Yorkshire Coast" contained all the most recent information, though every East-Yorkshire geologist knew that it did not. In examining a work on local geology it is always well to see where the author lived, for the surrounding country will be the best described. So it is here; the best part of the book is the description of the Middle and Upper Coal-measures, which are well developed in the neighbourhood of Bradford. For East Yorkshire and the coast the book is of little value.

The topography of the map requires no other guarantee than the name of the constructors for its excellency. The south-western part of the geological colouring derived from the Geological Survey maps is also very good. Nor can we complain when lack of published material prevents accuracy elsewhere, though it is a reason for regretting the slow publication of the Geological Survey maps which have been long ago completed; but when the whole of the Vale of Pickering is coloured Neocomian, and a patch of the same is placed in the south near Cave, scarcely an acre of rocks of that age being discoverable in the former, and none in the latter locality, one is led still more to regret that the author's map should be spoiled by his not knowing Mr. Hudleston's papers and relying on Prof. Phillips. But he has surely introduced a little mistake of his own, which will be very serious to visitors to the popular watering-places of Scarborough and Filey. The Castle Rock and Filey Brig are coloured —one Lower Oolite and the other Neocomian, whereas they are both what the author would call "Middle Colite"! It will take more than Mr. Bird to write a good "Geology of Yorkshire."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Leaves Injured at Night by Free Radiation

FRITZ MÜLLER, in a letter to me from Sta. Catharina in Brazil, dated August 9, supports the view which I have advanced with respect to leaves placing themselves in a vertical position at night, during their so-called sleep, in order to escape being chilled and injured by radiation into the open sky. He says: "We have had last week some rather cold nights (2° to 3° C. at sunrise), and these have given me a new confirmation of your view on the meaning of the nyctitropic movements of plants. Near my house there are some Pandanus trees, about a dozen years old; the youngest terminal leaves stand upright, whereas the older ones are bent down so as to expose their upper surfaces to the sky. These young leaves, though of course the most tender, are still as fresh and green as before; on the contrary, the older ones have suffered from the cold, and have become quite yellowish. Again, the leaves of *Oxalis sepium* were observed by me to sleep in a very imperfect manner during the summer, even after the most sunny days; but now, in winter, every leaflet hangs down in a perpendicular position during the whole night." It is a new fact to me that leaves should sleep in a more or less perfect manner at different seasons of the year.

CHARLES DARWIN

Red Rainbows

THE account in NATURE, vol. xxv. p. 431, of a pink rainbow seen from Mr. Tennyson's house, recalls to me a rainbow which I witnessed in July 1877 over the Lake of Lucerne from the promenade in front of the Schweitzerhof. The bow in question appeared at sunset, when the whole sky, east and west, was lit up with ruddy tints; and just before it faded out, the bow itself, which was a very brilliant one, showed only red and orange colours in place of its usual array of hues. No fewer than five supernumerary arcs were visible at the inner edge of the primary bow, and these showed red only. I fancy that the phenomenon cannot be very rare, from the circumstance that in pictures of the rainbow red and yellow are frequently the only colours set down by the artist. A few months ago Mr. C. Brocke Branwhite of Clifton showed me a very beautiful sketch in oils by his father, the late Mr. Charles Branwhite, a colourist of no mean power, in which a beautiful and exquisitely pellucid rainbow was drawn with red and yellow tints only. It may also be mentioned that in the copy of Rafael's "Madonna di Foligno" in the Dresden Gallery, there is a semi-circular red and yellow rainbow. I have not seen the original Foligno Madonna in Rome; and should be interested to know whether in this also red and yellow are the only tints accorded by the colourist.

Haslemere House, Clifton SILVANUS P. THOMPSON

IN your issue of the 8th inst. (vol. xxiv. p. 431) your correspondent "A. M." describes what he calls a "pink rainbow" seen by him at Aldworth, near Haslemere, and as a painter I am interested in his description, as it exactly corresponds with the same phenomenon as seen by me here, same date, and viewed with curiosity by myself and friends.

Corrie Hotel, Arran, September 11 DAVID MURRAY

Atoms

ALTHOUGH I am not an "eminent" authority, perhaps you will excuse my troubling you with the following extract from a paper read by me before the Philosophical Society of Glasgow in November, 1875, a copy of which paper I posted to the Editor of NATURE:—"I have long been of opinion that the most probable hypothesis of the origin of atoms is that there is only one kind of matter—ether or its constituents—and that atoms are merely congeries of units of ether circling at enormous speeds round each other, differently grouped, in different numbers, at different velocities, and at different distances, even as the different members of our sun systems. . . . The numbers of units in each similar atom need not be always the same; a few dozens more or less will not be appreciable by us. On the other hand, if a so-called element show a plurality of spectroscopic lines or hues, I do not think it at all doubtful that there is a plurality of units moving to produce these, since they thus show effects of different modes of moving of bodies; all our different states of sensual consciousness of colours are necessarily dependent on differences in the modes of moving of the agents that excite in us such plurality of lines and hues. As the motions of atoms, or rather of groups of atoms, excite in us sensations of sound, so the motions of units, or rather of groups of units, excite in us sensations of colour, and of course the lower-pitched movements of dark heat. Then again, we may hold that the more lines that persist in a spark or a sun, the less easily reducible are the portions of the elements showing them, as far as these lines' constituents are concerned—the lines being still undissociated material." (*Proc.* Phil. Soc. of Glas., vol. x. p. 61.) HENRY MUIRHEAD

Cambuslang, August 26

Luminous Phenomena on Rupture of Sea-Ice

IN my diary for January 20, 1881, occurs the following passage. I make no attempt to account for the phenomenon, but am certain it was not caused by any reflection of the lights on board the vessel:—

"Started from Christiania at about 2 a.m. in the *Nyland* steamer bound for Christiansand. At Krujero the steamer forced its way through the ice for half an hour till within about a mile of the land, where sleighs met it on the ice. The passengers and cargo were discharged or taken up on the ice, out of which we backed in close proximity to the *Kong Hacon*, which steamer had followed us in. A beautiful sunset and Arctic winter view, clear air, and rich sky, also a distant ship fast in the ice. The *Nyland* stopped at Arendal for the night, having got to the quay through much ice. We observe often phosphorescence or phosphorescence-like sparks and flashes in the ice as it is broken up by the steamer."

I think that the average thickness of the ice might have been about eight inches. I cannot give the temperature, but on the previous day at Christiania the thermometer indicated about 8° or 10° below zero Fahrenheit (about 40° Fahrenheit of frost). The diary from which the above extract is taken was kept jointly by myself and my travelling-companion, Mr. Winter, of the Indian Civil Service, who of course also saw the flashes referred to. I should like to have been able to talk the matter over again with him, but he is now in India. J. ALLEN ALLEN

[The question raised in this letter is a very interesting one. The phenomenon is possibly analogous to the electric flashes which are produced when loaf-sugar is crushed or when mica is rapidly split. It appears very improbable that it can be due to phosphorescent creatures in the water under the ice.—ED.]

Tidal Currents *versus* Wind Waves

IN NATURE, vol. xxiv. p. 286, a writer on "sea-shore alluvion" positively asserts that the travelling of sea beaches is due to wind-waves, and not to tidal currents, and calls a writer in the *Engineer* to task for having stated the latter. Notwithstanding this assertion, I would suggest that the writer in the *Engineer* is right. Twenty-five years ago, when an engineering student, I was taught that sea-beach travelling was due to wind-waves. Afterwards, while knocking about during fifteen years in the vicinity of the south and west coasts of Ireland, I noted facts that went to show that such a theory was not universally correct. This led me to study wind-action on the sea and lakes, also all I could find that had been written on the subject; the result being that as *good* evidence was so contradictory, no opinion could be come to from the evidence of others. But it was not till about ten years ago, when I was so circumstanced that I could properly study wave-action, and after six years' careful observation on the south-east coast of Ireland, that I found that tidal currents were the principal motive power; and on again reading what had been written on the subject, that I found that nearly all the advocates for the driftage of sea beaches by wind-waves had studied on beaches *where the most continuous and powerful winds acted in conjunction with the flow-tide current.* As the results of my observations have been published in the *Proceedings* of the Royal Irish Academy, English and Irish Institutions of Civil Engineers, the Geological Societies of London, Dublin, &c., during the last six or eight years, it is unnecessary to repeat them here. I would, however, point out that when there are only wind-waves and no tidal currents, the beaches as a general rule are banked up, but do not travel (the writer in NATURE seems to have observed this, but does not appear to see the importance of it). This may be seen in the tideless Mediterranean, as pointed out by the late Dr. Ansted in his paper on the Lagoons at the Delta of the Rhone; it may also be seen in Malcombe, or any other bay where there is a "head of the tide" but no tidal current; and in the different freshwater lakes, when the wind-waves are the *only* motive power. But wherever there are tidal currents acting on a coast the beach must travel. Such tidal currents are those that most perplex the erectors of groynes. If there was only the travelling augmented by wind-waves, the erection of groynes would be very simple; but, as a general rule, they are most necessary where there are strong tidal currents (or conflicting currents) due to the regular "flow" tide, "half counter" tides, or "on-shore" tides; which conflicting currents, combined with the action of wind-waves, let them be direct or as "ground swells," make up all the "cutting-out tides." The greater the complications the greater the "cutting out," and the more ingenious have to be the groynes. "Fulls" accumulate with the wind-waves, but rapidly disappear when the wind ceases. I presume the writer of the article in question is aware that the greatest rise of tide and the least current is at the "heads of the tides," while the least rise and greatest current is at the "nodal or hinge lines"; and I would be interested to know where permanent beaches accumulate in the latter localities, as from what I have seen those that form rapidly disappear when the wind ceases. G. H. KINAHAN

H.M. Geological Survey

Glaciation

IN NATURE, vol. xxiv. p. 364, I see a notice of a paper by Dr. Woeikoff on the glacial climate, in which it is shown that "the difference of mean temperature at the lower ends of glaciers (in different parts of the world) reaches fully 20°." This might be expected. The extent of glaciation depends not at all on mean or on winter temperature, but chiefly on summer temperature. *Perpetual* snow means *summer* snow, so that summer temperature is what determines the extent of the snow-fields remaining unmelted in the summer, and consequently of the glaciers which are fed by the snow-fields. The extent of glaciation is also much influenced by the amount of snow-fall. All this is stated in Forbes's "Norway and its Glaciers."

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim

Yellow Glass in Fog

SOME years ago I was staying at an hotel on the Lake of Constance. One morning a fog came on which completely obscured the opposite shore, but looking through a strip of yellow glass, which formed the border of the window, I was able, to my surprise, to see it distinctly. I presume the yellow glass choked the blue rays reflected by the fog, just as a Nicol's prism, held at the proper angle, chokes the rays reflected from the glass and enables us to see clearly the picture behind it. On my way home I stopped in Paris, and, happening to call on one of the principal opticians, mentioned the circumstance to him. He forthwith showed me a naval telescope provided with a cap at the eye end containing a yellow glass, which could be removed at pleasure. I should like to know if the same simple contrivance has ever been used in our own navy. R.

The New Museum of Natural History

IN your article on "The New Museum of Natural History" (NATURE, vol. xxiii. p. 549 *et seq.*) it is stated that the specimen of *Archæopteryx macrura* in the British Museum is headless. Will you permit me to draw attention to a nodule projecting from the slab in which the fossil lies, which bears a striking resemblance to the cerebral portion of a bird's skull? It is some years since I visited the museum, but I recollect feeling satisfied at the time that the nodule was the missing head, and worth while disinterring from its surrounding slate. E. H. PRINGLE

Calicut, July 31

[The nodule referred to by our correspondent is well known, and has been frequently criticised. Mr. John Evans, D.C.L., F.R.S., drew attention to it in an article published by him in the *Natural History Review*, 1865, pp. 415-421: "On portions of a cranium and of a jaw in the slab containing the fossil remains of the *Archæopteryx*." Although these fragments which occur in the slab in question undoubtedly belong to *Archæopteryx*, yet, as stated in our article, vol. xxiii. p. 551, "The original specimen described by Prof. Owen is headless," whereas the newly-discovered Berlin specimen has the head entire, and fairly well preserved, and still attached by the neck to the trunk.—ED.]

On the Velocity of Light

IN view of the experiments of Young and Forbes on the velocity of light, and of the article published by Lord Rayleigh on the subject, it may not be out of place to state as a fact which seemed at the time too evident to require special mention in my paper "On the Velocity of Light," that if the velocity of red and of blue light in air differed by as much as one-tenth of 1 per cent., the image of the slit which served as the source of light, instead of being white, would be spread out into a spectrum which could not fail to be observed. The total displacement in these experiments amounted to 133 millimetres; therefore, a difference of velocity of the red and the blue rays of 1·8 per cent. would necessitate a spectrum 2·4 millimetres in length.

It is needless to say that no spectrum was observed. These facts appear to be utterly irreconcilable with the conclusion drawn by Messrs. Young and Forbes.

ALBERT A. MICHELSON

Schluchsee, Prussia, August 28

Salmon in Preserved Rivers

HAVING resided for some time lately near one of our salmon rivers which is at present preserved by a club, I have at different times had conversations with men who knew it before its so-called preservation. They all say that when they were allowed to fish when and how they pleased, the supply of fish was much better in regard both to size and quantity. They account for it in the following manner:—Firstly, when the river was free, the people living near used to make spawning-beds for the fish, by placing large stones across the river and throwing gravel where deficient, and where gravel was naturally they used to loosen it with forks and remove the large stones. Secondly, they used to watch the fish at spawning time, and catch and kill all very large fish, say about 16 to 30 lbs. weight, after they had partially or wholly finished spawning, as they say the large fish destroy the salmon fry. Neither this nor the formation of spawning-beds is done at present. Would the above reasons account for the diminution in the size and number of salmon caught in our rivers? The diminution, in the river I speak of, cannot be accounted for by pollution, as the number of houses near enough to send their drainage into the river is too small to affect it, and as the river has a very quick fall and rocky bed, it is subject to such very rapid rises and falls in quantity of water that would prevent any settlement of noxious sediment. F. C. S.

New Seismometer

IN NATURE, vol. xxiv. p. 113, there is a notice of a new seismometer which has several advantages claimed for it. Might I suggest what seems an obvious and important improvement? As a rule pendulums cannot record vertical or oblique motions, and yet these are often the most necessary and valuable to record. 1. To do this, and yet as easily allow of lateral registration, I would say, support a heavy (leaden) ball of some 100 lbs. by a 30 or 40 feet spiral or rubber spring of suitable strength. It will be found that a very considerable amount of vertical play can take place, especially vertical effort, ere the ball can be affected, and that lateral play of the support will produce very little effect indeed, unless, as is most unlikely, the motion is prolonged and is *continuous* in one direction. 2. Around the sphere, and at a very short distance from its surface, radial rods actuated like the key-plugs of a cornet are supported, say at every 30° all over the surface, contact with any one of which will electrically record *time*, and the pencil attached to the plunger record distance of stroke on revolving paper attached to plunger-tube.

Asam, July 6 S. E. PEAL

THE BRITISH ASSOCIATION

THE actual number of persons who attended the York Meeting of the British Association, as announced at the last meeting of the General Committee, was 2556; divided between 272 old life-members, 27 new life-members, 312 old annual members, 175 new annual members, 1232 associates, 514 ladies, and 24 foreigners. The seven previous occasions on which this number has been exceeded were:—Newcastle-on-Tyne, 1863 (3335); Manchester, 1861 (3138); Liverpool, 1870 (2878); Bath, 1864 (2802); Glasgow, 1876 (2774); Dublin, 1878 (2578); Aberdeen, 1859 (2564). The number fell below 1000 at Cambridge, Plymouth, Southampton, Ipswich, Hull, and Swansea. 1280*l.* were paid out by the Council for scientific purposes after the last meeting, a larger sum than on any occasion since 1873; while between 1873 and 1861 that sum was always exceeded, and at Norwich, in 1868, it amounted to 1940*l.*

The following foreigners were present at the meeting:—Professrs Barker of Pennsylvania; Bergeron, Paris; Bojanowski; Carbonnelle, Brussels; Chemin, Paris; Craig, Johns Hopkins University, U.S.; Dohrn, Naples; Eads, St. Louis, U.S.; Gariel, Paris; Dr. Asa Gray, Harvard University; Halphen, Paris; Dr. Edwin Hall, Baltimore, U.S.; Hubrecht, Leyden; Prof. W. W. Johnson, Annapolis, U.S.; Prof. O. C. Marsh, Yale College; Moser, Berlin; Prof. H. A. Rowland, Baltimore; Stephanos, Paris; Sturm, Münster, Westphalia; Prof. H. M. Whitney, Beloit College, Wisconsin, U.S.A.

We ought to have stated in our report of the doings of the Association in our last number, that Prof. Huxley's lecture on Palæontology, which we gave in the same number, was delivered on the evening of Friday the 9th.

Nearly 350 papers or reports were read before the several sections. Of these the Physical and Mathematical Section received 89; the Chemical Section 49; Geology 59; Biology 79; Geography 16; Economic Science and Statistics 26; and Mechanical Science 29. Of the papers in Section A 23 related to Electricity; 21 were Mathematical; Optics claimed 12; Meteorology 11; Astronomy and Physical Geography 12; Heat 5; and miscellaneous physical subjects 5. Of course prominent subjects of interest were electric lighting, electric measurements, and Faure's cells. Such subjects were thoroughly ventilated by discussions both in Section and Committee, and more intimately during the thousand and one opportunities for interchange of ideas which occurred in the afternoon and evening. Again, the storage of energy, the nature of meteoric dust, the existence of intra-Mercurial planets, the lunar disturbance of gravity, the nature of colours, and the contact theory were each severally discussed. Among the 49 Chemical papers several theoretical matters were introduced—specially the atomic theory, chemical nomenclature, vapour densities, molecular weights, Mendeleeff's law, and molecular attraction; processes of analysis and technical operations were described, and new experiments were explained. Of course a good deal of the geological work bore reference to Yorkshire, especially to the evidences of glacial action which it presents. The geological papers were of a very general and interesting character, and embraced every branch of the subject, from the vulcanology of Japan to the minerals found at Laurium, and from the Cheshire salt beds to the evolution of the Plesiosaurus. Section D furnished a larger number of papers than any other Section except A, but we must bear in mind that it really consists of three sub-sections, devoted respectively to Zoology and Botany, Anatomy and Physiology, and to Anthropology. The latter subject has developed extraordinarily, more than half the papers contributed to the Section were read before this Sub-Section. The report of the Anthropometric Committee, which evoked a good deal of discussion, was read in the Section of Economic Science and Statistics. In this section Mr. Grant Duff delivered a very able address, which was warmly received. A tendency to introduce matter which has a political bearing and which may be discussed from a political standpoint is sometimes apparent in this section, and should be carefully guarded against by the Committee. The Mechanical Section furnished some important reports on patent laws, wind pressure, tides in the English Channel, and the steering of screw steamers. Here also were papers on the different forms of electric lamp, the electrical transmission of force, and the illumination of lighthouses.

Thus it will be seen that all the prominent subjects of science have received their share of attention, and at the hands of one or other of the sections have been either expanded or discussed. The interchange of ideas has been incessantly going on, and many men have become acquainted who might otherwise have remained unknown to each other for years. Some 500 scientific men have been gathered together from various parts of the British Islands; and some 2000 persons have been brought face to face with the burning scientific questions of the day, and have had new interests awakened, or old knowledge resuscitated. There can be little doubt as to the

expediency of continuing the work of the Association, if it keep at all near to the standard of the York meeting. The German Society, founded nine years before our Association, and its prototype, still continues to meet annually; and scientific congresses are becoming more and more general every year in Europe.

Canada has been proposed as the place of meeting for 1885. The difficulties of time and place and expense are far less formidable than they appear at the outset. Great facilities would be put in our way by steamboat companies; and, once arrived, the Colony would receive us with open arms. Again, the Americans wish us to join their Association on some convenient occasion, and *àpropos* of this a practical American observed a few days since, "From the moment you set foot on American soil to the moment of departure, you should not put down a cent." One other fact remains to be noticed in regard to the York meeting. *Thirty-four* local societies and institutions were represented at the meeting by forty-nine delegates; and the Council have under consideration the conditions under which these delegates were present, and their object in attending. Cannot the Association do something for them? Cannot some organisation be introduced to influence the local societies through the Association, and cannot a committee of delegates be appointed to discuss matters connected with their respective institutions?

REPORTS

Report of the Committee, consisting of Dr. J. H. Gladstone, Dr. W. R. E. Hodgkinson, Mr. W. Carleton Williams, and Dr. P. P. Bedson (secretary), appointed for the purpose of investigating the Method of Determining the Specific Refraction of Solids from their Solutions.—Mr. P. P. Bedson, D.Sc., read the Report, and stated that the object of this report was to submit to further examination the method proposed some years ago by Messrs. Gladstone and Dale. According to this method the specific refraction of a solid may be deduced from that of a solution containing it, provided the specific refraction of the solvent is known, as also that of the solution and the composition of the solution. The experiments, of which an account is given in the report, appear to confirm this statement of the above-mentioned authors. The first case examined was that of liquid phenol. Its specific refraction for a ray of light of infinite wavelength was determined at 40° and 45°. The values obtained for the specific refraction of liquid phenol at 40° and 45°, viz., ·4850 and ·4848, are closely approximate to that obtained by Brühl (*Journ.* Chem. Soc., abst., 1880, p. 782) for phenol at 20°, viz., ·4862. Further, these results agree very well with the mean of the specific refractions obtained from the alcoholic and acetic acids solutions. The specific refraction of rock-salt in the solid state has also been determined and compared, with its specific refraction as deduced from its aqueous solutions; and it was found that the specific refraction obtained from the aqueous solution is substantially the same as that obtained from a prism of rock-salt. Further, the specific refractions of fused borax and boric acid have been determined, and in these cases also the specific refraction obtained from their aqueous solutions was found to be approximately the same as the specific refractions of fused borax and boric acid. The indices of fused borax and of fused boric acid were determined by means of prisms of these materials, which were cast in a mould of silver plates and afterwards ground and polished.

Report of Committee on Meteoric Dust, by Prof. Schuster.—This Committee was appointed for the double purpose of examining the observations hitherto recorded on the subject of meteoric dust and of discussing the possibility of future more systematic investigations. With regard to the first point we note that in a paper presented to the Royal Astronomical Society in 1879, Mr. Ranyard has given what appears to be a pretty complete account of the known observations as to the presence of meteoric dust in the atmosphere. It appears that in the year 1852 Prof. Andrews found native iron in the basalt of the Giant's Causeway. Nordenskjöld found particles of iron which in all probability had a cosmic origin in the snows of Finland and in the ice-fields of the Arctic regions. Dr. T. L. Phipson, and more recently Tissandier, found similar particles deposited by the winds on plates exposed in different localities. Finally, Mr. John Murray discovered magnetic particles raised from deposits at the bottom of the sea by H.M.S. *Challenger*. These particles were examined by Prof. Alexander Herschel, who agreed with Mr. Murray in ascribing a cosmic origin to them. For fuller details and all references we must refer to Mr. Ranyard's paper. There cannot be any doubt that magnetic dust, which in all probability derives its origin from meteors, has often been observed, and the question arises, in what way we can increase our knowledge on these points to an appreciable extent. A further series of occasional observations would in all probability lead to no result of great value, unless they were carried on for a great length of time in suitable places. Meteoric dust, we know, does fall, and observations ought if possible to be directed rather towards an approximate estimate of the quantity which falls within a given time. Difficulties very likely will be found in the determination of the locality in which the observations should be conducted. The place ought to be sheltered as much as possible against any ordinary dust not of meteoric origin. The lonely spots best fitted for these observations are generally accessible to occasional experiments only, and do not lend themselves easily to a regular series of observations. Nevertheless experiments continued for a few months at some elevated spot in the Alps might lead to valuable results. The Committee would like to draw attention to an instrument which is well fitted for such observations. It was devised by Dr. Pierre Miquel for the purpose of examining, not the meteoric particles, but organic and organised matters floating about in the air. A description, with illustrations, will be found in the *Annuaire de Montsouris* for 1879. Two forms of the instrument are given. In the first form, which is only adapted to permanent places of observations, an aspirator draws a quantity of air through a fine hole. The air impinges on a plate coated with glycerine, which retains all solid matter. By means of this instrument we may determine the quantity of solid particles within a given volume of air. The second, more portable, form does not allow such an accurate quantitative air analysis. The instrument is attached to a weathercock, and thus is always directed against the wind, which traverses it, and deposits, as in the other permanent form, its solid matter on a glycerine plate. An anemometer placed in the vicinity serves to give an approximate idea of the quantity of air which has passed through the apparatus. These instruments have been called aëroscopes by their inventor. It is likely that the second form given to the apparatus will be best fitted for the purpose which the Committee has in view.

Seventh Report of the Committee on Underground Water Supply, consisting of Prof. E. Hull, the Rev. H. W. Crosskey, Capt. Douglas Galton, C.B., Mr. James Glaisher, F.R.S., Prof. G. A. Lebour, Mr. W. Molyneux, Mr. G. H. Morton, Mr. W. Pengelly, Prof. J. Prestwich, Mr. James Plant, Mr. James Parker, Mr. T. Roberts, Mr. S. Stooke, Mr. G. J. Symons, Mr. W. Whitaker, was read by Mr. C. E. de Rance, of H.M.'s Geological Survey, the Secretary.—The Committee was appointed in 1874 at the Belfast Meeting of the Association, with Prof. Hull, LL.D., F.R.S., as Chairman, and Mr. De Rance, F.G.S., as Secretary and Reporter; its six published reports occupy 125 pages of the Society's *Proceedings*, and the results of the investigations of the Committee show that the Permian, Triassic, and Jurassic formations of England and Wales are capable of absorbing from five to ten inches of annual rainfall, giving a daily average yield of from 200,000 to 400,000 gallons per square mile per day. The area occupied by these formations is, in round numbers, Permian and Trias, 8600 square miles, and Oolites, 6600 square miles, capable of yielding 1720 millions and 1320 million gallons respectively, at the lowest rate of absorption, or, united, a supply for 100 million people, at thirty gallons a head. Mr. De Rance then described the water-bearing condition of the Yorkshire area, and stated that the investigation would now be extended to all the porous rocks of South Britain.

Report on the Earthquakes of Japan, by Prof. John Milne.—The author arrives at the following conclusions:—1. That the actual back and forth motion of the ground is seldom more than a few millimetres (usually not equal to 1mm.), even though chimneys have fallen. 2. The motion usually commences gently, but is very irregular. 3. The number of vibrations per second usually vary between three and six. 4. During one shock *its direction* of motion may be irregular. 5. East and west vibrations, as recorded in Yedo, have in some cases been shown by time observations to have travelled up from the south. 6. Many of the shocks which visit Yedo appear to have come

from the district which is faulted, and which shows distinct evidence of *very recent* elevation.

Second Report of the Committee consisting of Prof. P. M. Duncan and Mr. G. R. Vine, appointed for the purpose of reporting on Fossil Polyzoa; drawn up by Mr. Vine.—The order is divided into three subdivisions :—

1. *Cheilostoma*, Bark. = *Celleporina*, Ehrenberg.
2. *Cyclostomata*, ,, = *Tubuliporina*, Milne-Ed., Hagenow, Johnston.
3. *Ctenostomata*, ,,

The following terms are used in this Report in describing the genera :—

ZOARIUM.—"The composite structure formed by repeated gemmation" = Polyzoarium and Polypidom of authors.

ZOŒCIUM or cell.—"The chamber in which the Polypide is lodged."

CŒNŒCIUM.—"The common dermal system of a colony." Applicable alike to the "Frond," or "Polyzoary," of Fenestella, Polypora, Phyllopora, or Synocladia; or to the associated Zoœcia and their connecting "interstitial tuberuli," of Ceriopora, Hyphasmapora, and Archæopora, or species allied to these.

FENESTRULES.—The square, oblong, or partially rounded openings in the zoarium—*connected by non-cellular dissepiments*—of Fenestella, Polypora, and species allied to these.

FENESTRÆ applied to similar openings, whenever connected by the general substance of the zoarium—as in Phyllopora, Clathropora, and the Permian Synocladia.

BRANCHES.—The CELL-bearing portions of the zoarium of Glauconome, Fenestella, Polypora, or Synocladia; or the offshoots from the main stem of any species.

GONÆCIUM.—"A modified zoœcium or cell, set apart for the purposes of reproduction."

GONOCYST.—"An inflation of the surface of the zoarium in which the embryos are developed." Modern terms from the Rev. Thos. Hincks.

Report of the Committee on Erratic Blocks, drawn up by the Rev. B. W. Crosskey.—Many additional instances of the occurrence of erratic blocks were recorded. Particulars were given respecting granite and sandstone boulders found while excavating for the new dock at Maryport, Cumberland. The granite specimens vary in size from small pebbles to a ton in weight, and are rounded. The New Red Sandstone boulders vary from half a ton to two tons or more, and have sharp angles. The nearest granite occurs in the Kirkudbrightshire Hills, on the other side of the Solway, fifteen or twenty miles distant; the New Red Sandstone is the stone of the district. A boulder of Shap granite found near Filey has been removed to the University Museum, Oxford. It rested on Oolitic strata at a height of about 150 feet above the sea. The nearest place where a granite of the same character is found is 108 miles distant, bearing west-north-west from Filey. The attention of the committee was drawn by Prof. T. McK. Hughes to a boulder of porphyritic hornblende diabase, near the centre of Anglesea. It is chiefly interesting as having been considered an inscribed stone, but the supposed characters are entirely due to rock structure. A detailed description of the great erratic called the "Holy Stone," at Humberstone, Leicestershire, was given. Its weight is about twenty-one tons. It rests on a denuded surface of the Rhætic formation. The height from which it travelled is about 400 feet above the sea, and is situated six miles north-west. The present height at which the block now rests is about 240 feet above the sea, and there is a river valley between these two points, running at right angles to the line of transit of the block, which is only 110 feet above the level of the sea. Various groups of boulders in Leicestershire were also described, some containing millstone grit blocks derived from Derbyshire, which must have travelled about thirty-five miles. A catalogue of 191 blocks in the parish of Ashwell, County of Hertford, was given. None of these blocks are local. Their general derivation is from the Oolites of the Midlands and from the Carboniferous and other rocks of more northern districts. The report concluded with an appeal to local observers to give assistance in cataloguing the rapidly-disappearing erratic blocks of the country.

Report on Thermal Conductivity of Certain Rocks, showing especially the Geological Aspects of the Investigations, by Prof. A. S. Herschel and Prof. Lebour.—This is the seventh and final Report of the Committee, and comprises a *résumé* of the results given in the preceding ones, with numerous additions and corrections. A bibliographical list of all papers on the subject, by Mr. J. T. Dunn, B.Sc., is given as an appendix. The apparatus and specimens employed during the investigations of the Committee are preserved in the museum of the College of Physical Science at Newcastle-on-Tyne.

SECTION A—MATHEMATICAL AND PHYSICAL

On the Possibility of the Existence of Intra-Mercurial Planets, by Balfour Stewart, LL.D., F.R.S.—It is a somewhat frequent speculation amongst those who are engaged in sun-spot research to regard the state of the solar surface as influenced in some way by the positions of the planets.

In order to verify this hypothesis observers have tried whether there appear to be solar periods exactly coinciding with certain well-known planetary periods. This method has been adopted by the Kew observers (Messrs. De La Rue, Stewart, and Loewy), who had an unusually large mass of material at their disposal, and they have obtained from it the following results :—

1. An apparent maximum and minimum of spotted area approximately corresponding in time to the perihelion and aphelion of Mercury.

2. An apparent maximum and minimum of spotted area approximately corresponding in time to the conjunction and opposition of Mercury and Jupiter.

3. An apparent maximum and minimum of spotted area approximately corresponding in time to the conjunction and opposition of Venus and Jupiter.

4. An apparent maximum and minimum of spotted area approximately corresponding in time to the conjunction and opposition of Venus and Mercury.

The Kew observers make the following remarks upon these results :—

"There appears to be a certain amount of likeness between the march of the numbers in the four periods which we have investigated, but we desire to record this rather as a result brought out by a certain specified method of treating the material at our disposal than as a fact from which we are at present prepared to draw conclusions. As the investigation of these and similar phenomena proceeds, it may be hoped that much light will be thrown upon the causes of sun-spot periodicity."

The Kew observers have likewise produced evidence of a different kind in favour of the planetary hypothesis, for they have detected a periodicity in the behaviour of sun-spots with regard to increase and diminution apparently depending upon the positions of the two nearer planets, Mercury and Venus. The law seems to be that as a portion of the sun's surface is carried by rotation nearer to one of these two influential planets, there is a tendency for spots to become less and disappear, while on the other hand, when it is carried away from the neighbourhood of one of these planets, there is a tendency for spots to break out and increase.

But whatever truth may be in these conclusions, it appears to be quite certain that periodical relations between the various *known* planets will not account for *all* the sun-spot inequalities with which we are acquainted. They may account for some, but certainly not for all. For there are solar inequalities of short duration which, presuming them to be real, can only be accounted for on the planetary hypothesis by supposing the existence of several unknown intra-Mercurial planets.

Indeed these short-period inequalities in sun-spots and the allied phenomena of terrestrial magnetism and meteorology have so augmented in number of late years as to make some observers inclined to question their reality; while others again resort to the above-mentioned hypothesis, and attribute them to intra-Mercurial planetary agency.

The method to be pursued in detecting the existence of inequalities will be easily understood by an illustration. Suppose that we had in our possession extensive records of the temperature of the earth's atmosphere at some one place in middle latitudes, and that, independently of astronomical knowledge, we were to make use of these for the purpose of investigating the natural inequalities of terrestrial temperature. We should begin by grouping the observations according to various periods taken, say, at small but definite time-intervals from each other. Now if our series of observations were sufficiently extensive, and if some one of our various groupings together of this series

should correspond to a real inequality, we should expect it to exhibit a well-defined and prominent fluctuation, whose departures above and below the mean should be of considerable amount.

Suppose, for instance, that we have twenty-four points in our series, and that we group a long series of temperature observations in rows of twenty four each, the time-distance between two contiguous members of one row being one hour. The series would thus represent the mean solar day, and we should without doubt obtain from a final summation of our rows a result exhibiting a prominent temperature fluctuation of a well-defined character, which we might measure (as long as we keep to twenty-four points) by simply adding together all the departures of its various points from the mean, whether these points lie above or below; in fine, by obtaining the area of the curve, which is the graphical representation of the inequality above and below the line of abscissæ taken to represent the mean of all the points. Suppose next that, still keeping to rows of twenty-four, we should make the time-interval between two contiguous members of a row somewhat different from one hour, whether greater or less, we should now in either case obtain a result exhibiting, when measured as above, a much smaller inequality than that given when the interval was exactly one hour; and it is even possible that, if our series of observations were sufficiently extensive, we should obtain hardly any traces of an inequality whatever.

In fine, when each row accurately represented a solar day, the result would be an inequality of large amount; but when each row represented a period either slightly less or greater than a day, the result would be an inequality of small amount. This process, as far as I have described it, is not new, inasmuch as something of this kind must be pursued in all attempts to detect inequalities. In the present instance we should by its means, after bestowing enormous labour in variously grouping, in accordance with a great number of periods taken at small intervals from each other, obtain definite results. These might be graphically represented in the following manner:—

The line of abscissæ might be taken to denote the exact values of the various periods, forming a time-scale, in fact, while the ordinates might represent the areas or summations obtained as above by employing these various periods. There would thus be in the case now used for illustration a very prominent peak, corresponding to twenty-four hours, which would fall off very rapidly on either side.

By means of the process now described we should at length, after enormous labour, obtain a graphical result, showing the exact position in the time-scale of the observed maximum inequality. In conjunction with Mr. William Dodgson, I have devised a method by which this labour is very greatly reduced, and the process so modified has been applied by us in order to determine whether there be inequalities of short period in the observed areas of the sun-spots occurring on the visible hemisphere of the sun. We have detected an inequality of this nature corresponding in period to 24·011 days, which, when subjected to a certain purifying treatment, appears to us to exhibit the marks of a true periodicity. But it has been suggested by Prof. Stokes that a method of this nature for detecting inequalities might with greater propriety be employed as a crucible for testing the value of some hypothesis introduced into it from without.

Acting upon this suggestion I have ventured to introduce the planetary hypothesis, and to ask whether the above sun-spot inequality of short period may not in reality be caused by an intra-Mercurial planet. It is quite easy to put this hypothesis to a test, taking for our guidance the results obtained by the Kew observers. For what do these results exhibit? In the first place they exhibit the probability of a sun-spot inequality corresponding to the period of Mercury round the sun; and in the next they exhibit the probability of similar inequalities corresponding to the synodic period of Mercury and Venus, and to the synodic period of Mercury and Jupiter.

Now if there be an intra-Mercurial planet of period 24·011 days, it will have the following synodic periods:—

With Mercury	... ...	33·025 days.
With Venus	... ...	26·884 days.
With Jupiter	... ...	24·145 days.

In conjunction with Mr. Dodgson I have applied the above method of analysis with the view of ascertaining whether there be well-marked sun-spot inequalities nearly corresponding to these periods, and we have obtained the following results:—

A very prominent inequality of period	...	32·955 days.
A very prominent inequality of period	...	26·871 days.
A less prominent inequality of period	...	24·142 days.

It will thus be noticed that there are prominent sun-spot inequalities, the periods of which agree very well with the synodic periods of the supposed planet with Mercury, Venus, and Jupiter, more especially if we bear in mind that this is only a first approximation.

The test, however, is not yet complete. Referring once more to the results of the Kew observers, it will be noticed that we have approximately maxima of sun-spot areas when Mercury and Venus, or when Mercury and Jupiter are in conjunction. Now if we assume that there is an intra-Mercurial planet of period 24·011 days, we are as yet unable to assign its exact position in ecliptical longitude at any moment. We know its period, and we may presume that it has considerable excentricity, but we know nothing else. We may, however, assume as most probable that the maximum point of the inequality of period 32·955 days corresponds to the conjunction of the planet with Mercury, the maximum point of the inequality of period 26·871 days to its conjunction with Venus, and the maximum point of the inequality of period 24·142 days to its conjunction with Jupiter. On this assumption, and knowing the average rate of motion of the planet in its orbit, we may deduce approximately its position at a given epoch independently from each of the three synodic periods above mentioned, and these positions ought to agree together, if our hypothesis be correct.

I have done this approximately, but am not able to bring exact figures before this meeting. The agreement is as great as can be expected, bearing in mind that we know only the average rate of motion of the planet, and not the variations of its rate, inasmuch as we are ignorant of its excentricity. I think I may state that three independent values of its position corresponding to January 1, 1832, will be obtained, and that the mean difference of a single value from the mean of the whole will probably not be more than twenty degrees. It would thus appear from this investigation that the evidence is in favour of the sun-spot inequality of 24·011 days being due to an intra-Mercurial planet. Of course a single research of this nature is insufficient to establish a theory of this importance, but as there are several short-period solar inequalities, the same method may be pursued for each, an operation which demands nothing but time and labour. It appears to me of great importance that these short-period solar inequalities should be systematically examined after this method.

The Effects of Gulf Streams upon Climates, by Dr. S. Haughton.—The author said that the Gulf Stream, and its counter current, the Labrador Current, produced important effects upon climate. The northern hemisphere was warmer than the southern from lat. 0° to lat. 30°, and it was colder than the southern from lat. 40° to 60°. The higher temperature of the southern hemisphere in the temperate latitudes was explained by the existence of three gulf streams in that hemisphere, while there was only one in the North Atlantic, and a partial one through Behring's Straits in the northern hemisphere. The general climatal effect of the Gulf Stream was therefore to make the annual range of temperature less, but it had no effect whatever upon summer heat, or upon the fruiting of plants and trees, that required a given July temperature for reproduction. The January temperatures in the North Atlantic at 70° were raised by the Gulf Stream, whilst the July temperatures remain unaffected. The effect of the cold currents, which were indirectly caused by the warm currents to preserve the proper condition of equilibrium, was nothing at all upon the January temperatures, but they lowered the July temperatures. The effect of the cold water was to lower the July temperature and to leave the January untouched, and the effect of the warm current from the south was to raise January and to leave July unaltered.

The Photographic Spectrum of Comet B 1881, by Dr. W. Huggins.—The author stated that in 1868 he applied the spectroscope to the light of comets, the result of his observations being to show the presence of carbon probably in conjunction with hydrogen in the cometary matter. Since then, until the present year, no comet of sufficient brilliancy to admit of observations being made had appeared. On the evening of June 23 last he directed the spectroscope to the head of Comet B with an exposure of an hour; and on the following night he obtained a second photograph with an exposure of an hour and a half. As it happened, the photograph which was the result of the longer period of exposure was the weaker of the two, but, taken together, an examination of the bands confirmed his

previous observations, and showed that part of the light of the comet was reflected sunlight and part original light; and further, that carbon was present in the cometary matter, with strong evidence also of the presence of nitrogen, in addition to carbon and hydrogen.

The Electric Discharge through Colza Oil, by A. Macfarlane, D.Sc., F.R.S.E.—The electrical properties of colza oil which I have examined are its dielectric strength and some phenomena which accompany the passage of the spark. By the dielectric strength of a substance I mean the ratio of the difference of potential required to pass a spark through air under the same conditions. The electrodes used were two parallel brass plates each 4 inches in diameter. When comparing the gases the standard distance of the plate chosen was 5 mm. In the case of liquids it is convenient to observe for a shorter distance, and reduce the result by the law which previous experiments of mine have established, namely, that in the case of the discharge between parallel plates through a liquid dielectric the difference of potential required is proportional to the distance between the plates (*Trans.* R.S.E., vol. xxix. p. 563). One set of observations gave the ratio for colza oil to be 2·7, another gave 2·5. Hence 2·6 may be taken. I have now obtained the following table of dielectric strengths for liquids (1 being unity).

Substance.	Dielectric Strength.
Paraffin oil	3·7
Oil of turpentine	4·0
Paraffin liquefied	2·4
Olive oil	3·5
Colza oil	2·6

The specific gravity of the colza oil is ·91. The passage of the spark was accompanied by the formation of gas bubbles, but there was no deposition of solid particles. As the 4-inch plates were placed horizontally in the oil a bubble produced by the discharge was prevented from escaping by the upper plate. When the upper plate is again electrified such a bubble behaves in the following manner. If it is large enough it will extend itself somewhat like an hour-glass between the plates, but if it is smaller it takes the form of an acorn with a flat base, the base resting on one or other of the plates. When the upper plate is charged positively the bubble is repelled so as to place its base on the lower plate; when the electricity is charged to negative the bubble remains with its base on the upper plate. A reversal of the order of charging did not change the effect. After a few electrifications a sufficient number of solid particles collect to form a chain, and thus interferes with the phenomenon, the bubbles then being lengthened out in a remarkable manner, but never repelled to the lower plate. When the upper plate was charged negatively, gas bubbles appeared to me to rise from the lower plate, as if they had been formed there. To test this point further I took some sparks between two smaller disks placed vertically in the oil. The gas-bubbles were observed to rise up at the negative surface as if they had been formed at the positive surface, and had been repelled or carried straight across, and then rose up at the negative surface. When the spark was taken between two points bent at right angles to two rods dipping into the oil, the bubbles were observed to shoot out in the direction from the positively charged point, and to circulate round the earth-rod some time before rising to the surface. These phenomena indicate that the bubble is positively electrified.

On the Electric Conductivity and Dichroic Absorption of Tourmaline, by Prof. Silvanus P. Thompson.—The electric conductivity of tourmaline differs in different directions; being, according to the author's experiments, a minimum along the optic axis. Tourmaline also possesses the optical property of dichroism, its absorption being a maximum for rays parallel to the axis, and greater for blue rays than for red, equal thicknesses of crystal being considered. According to the electromagnetic theory of light, bodies which are good conductors of electricity should be opaque to light. The author has in the August number of the *Philosophical Magazine* rewritten the equations of Maxwell's electromagnetic theory for the case of crystalline media possessing different conductivities in different directions. From these equations it appears that in tourmaline and negative uniaxial crystals electric displacements at right angles to the axis will be more absorbed than electric displacements parallel to the axis. This accounts for the well-known greater absorption of the ordinary ray, provided the views of Stokes and Fresnel are correct, that these displacements are at right angles to the so-called plane of polarization. The difference of velocity between rays of different colour accounts for the difference of absorption being greater in that direction in which the conductivity is a minimum. It was also pointed out that in positive uniaxial crystals, in which the electric conductivity is a maximum along the axis, there will be maximum absorption of the extraordinary ray, and there will be least opacity along the axis. Smoky quartz and magnesic platinocyanide fulfil the latter condition. Specimens of tourmaline cut into cubes to show the colours in different directions were shown, and also specimens of magnesic platinocyanide and of herapathite. Mechanico-optical models were also shown illustrating the theory; a tourmaline being represented by a cube built up of layers of glass and wire-gauze. In conclusion it was shown that crystals in which the electric conductivity differs in three different directions will exhibit *trichroism*; and that di- or tri-chroic absorption is a general property of all coloured crystals other than those of the cubical system.

On the Application of Electricity to the Localisation of a Bullet in a Wound, by W. H. Preece.—The author showed how an electric current could be made an invisible and immaterial probe localising the position of a bullet in the human body without touching or giving the slightest sensation of pain. The conception of using electricity alone as the tool occurred to Prof. Graham Bell in Washington, who at once telegraphed to the author to consult him in reference to the use of Hughes' induction balance. In order to apply this apparatus to the localisation of a bullet in a wound, Prof. Hughes recommended that a pair of exploring coils should be made movable and portable, in order that they might be moved over the body of the wounded man. If the coils were brought within three inches of the bullet its presence could be detected, the direction in which the bullet was situated could be determined by observing the position of maximum sound, for in that position the bullet would be in a line with the axis of the coil. In order to ascertain the depth of the bullet a similar bullet is moved along in the direction of the axis of the other coil until neutrality is obtained; the depth of the trial bullet then will be equal to the depth of the buried one.

On the General Coincidence between Sun-spot Activity and Terrestrial Magnetic Disturbance, by the Rev. F. Howlett, F.R.A.S.—The object of this paper was to inquire how far solar activity, more especially as regards sun-spots, is wont to be accompanied by terrestrial magnetic disturbances, as recorded by the automatic magnetic declination curves at Kew and Greenwich. The data for such an investigation were furnished by comparisons instituted between the most striking instances of sun-spots gathered out of a long series of solar observations carried on by Mr. Howlett from the year 1859 to the present epoch, and the synchronous conditions of the magnetic curves at the observatories above mentioned. The telescopic drawings of the spots were obtained with an achromatic of three inches aperture by Dollond, of forty-eight inches focal distance, projecting the sun's image on a large white screen in a darkened chamber. By employing a Huygenian eyepiece magnifying 120 linear, and placing the screen at the distance of five feet two inches from the eyepiece, a very distinct image of the sun was obtained of about five feet four inches in diameter, and of which every inch corresponded to just 30″ of the celestial arc. Not only were the measurements of all the solar phenomena rendered thereby exceedingly easy, but the conditions of amplification, illumination, and definition of details were combined in about the best possible manner for the observer's purpose, which was to maintain an accurate record of the solar spots, and very frequently of the faculæ also, on a large scale, and which have been collected into five volumes and presented to the Royal Astronomical Society. The comparisons commence with the very remarkable and cyclonic group of August, 1859, which was uniquely distinguished by the remarkable outburst of intense white light, far brighter than the photosphere itself, which fortunately was witnessed by the late Messrs. Carrington and Hodgson on the forenoon of September 1, but which Mr. Howlett missed seeing by only a few minutes, having completed his drawings, and left the telescope. Other striking and, if they may be so termed, crucial groups were compared with the magnetic records—very notably the great spot of October, 1865, engravings of which may be found in the volume of the *Proceedings* of the Royal Astronomical Society for the year last mentioned, as also the large groups of February, 1870, which were observed and drawn on the occasion of the recurrences by revolution of the same groups in the three consecutive months of February, March, and April of that year, and on the last of which months the total displacement, at one and the same time,

of the solar photosphere—or in other words, the total area occupied by the sun-spots—was no less than five thousand two hundred million square miles, or about twenty-seven times that of the superficies of the earth! So again in August and September, 1870, immense groups, occupying from four to five thousand million square miles, were observed to make two consecutive revolutions, and on the latter of which two occasions a beautifully enlarged photograph of the sun, twenty-four inches in diameter, was made by Mr. Titterton of Ely, under the auspices of the late Canon Selwyn, and exhibited to Section A. On all these occasions great magnetic disturbances, amounting often to absolute magnetic storms, were unequivocally manifested; and in fact out of twenty-four comparisons instituted, the following is the summary of results, as showing the coincidence of extensive solar activity and synchronous magnetic disturbances:—

Intensely	5	
Very decidedly	3	
Decidedly	9	= 21 affirmatively
Moderately	3	
Negatively (no spots, no storms) ...	1	
Questionable	1	
Contradictory	2	3 contradictory
	24	

Thus then, from the data collected, it would certainly appear that marked periods of solar activity are wont to coincide with marked periods of terrestrial magnetic disturbances; but yet from a careful comparison of the days and hours of the magnetic records appealed to, it also appeared that the disturbances were manifested in a variety of ways, not only as regarded the extent of the magnetic excursions of the needle, the rapidity of the oscillations, or the persistency of the more moderate disturbances, but also they were found to follow at considerably different intervals of time after the commencement of the observed solar outbursts. With respect, lastly, to reactionary influences, Mr. Howlett stated, on the authority of Mr. Whipple, the director of the Kew Observatory, that on the occasion of the perihelion passage of comet *b* 1881, on the 16th day of June last, the terrestrial magnetic curves were unusually quiescent.

On Artificial Flight, by Fred. W. Brearey.—The author proceeded to argue that the weight of the bird plays an active part in its flight, and that this result arises from the action of that portion of the pectoral muscle which depresses the wing. So great is the tension of this muscle that it is highly probable that, in the case of those long-winged and heavy birds which are able to fly without apparently moving a feather, the wings are kept extended against the resistance of the air underneath without any voluntary effort of the bird. Its weight pressing upon the air causes this muscle to expand in raising the wing, and aids in the effect of the downward stroke by its contraction. The author exhibited a model with wings 4 feet from tip to tip and 3 feet 2 inches from head to tail. The wings are moved by M. Penaud's plan of strands of india-rubber previously put into a state of tension, which in unwinding create a flapping of the wings. By an india-rubber cord attached to the under part of the wing and passing under the shaft to which the mechanism is attached an equilibrium between the two forces is attained; that is to say, the india-rubber strands are wound up to that extent that the wings in rising stretch the india-rubber cord—or, as the author calls it, the pectoral cord—until one force neutralises the other; so that, held in the hand, there is no action. When liberated, and committed to the pressure of the air, the weight of the model causes the wings to be elevated, and therefore stretches the pectoral cord, which in its contraction assists the power derived from the twisted rubber in depressing the wings against the weight of the model. During this action the flight is well sustained for 40 feet or more. The author states that an apparatus of the nature of a longitudinal parachute was liberated from a balloon which rose from Woolwich arsenal, and it travelled back, by the aid of gravity alone, to the arsenal, a distance of half a mile. From this he argued that if the fabric can be manipulated so that propulsion also can be imparted to it, then some encouraging results would be likely to follow. He showed a model of large size upon this principle, and how, by the action of the wing-arms, a wave is transmitted from head to tail along a loose surface in shape like a kite. This loose surface requires a fall before it can be inflated by the air underneath; the wave-motion of the wings is then found adequate to its propulsion.

On the Arrestation of Infusorial Life, by Prof. Tyndall.—Three years ago I brought with me to the Alps a number of flasks charged with animal and vegetable infusions. The flasks had been boiled from three to five minutes in London, and hermetically sealed during ebullition. Two years ago I had sent to me to Switzerland a batch of similar flasks containing other infusions. On my arrival here this year 120 of these flasks lay upon the shelves in my little library. Though eminently putrescible, the animal and vegetable juices had remained as sweet and clear as when they were prepared in London. Still an expert taking up one of the flasks containing an infusion of beef or mutton would infallibly pronounce it to be charged with organisms. He would find it more or less turbid throughout, with massive flocculi moving heavily in the liquid. Exposure of the flask for a minute or two to lukewarm water would cause both turbidity and flocculi to disappear, and render the infusion as clear as the purest distilled water. The turbidity and flocculi are simply due to the coagulation of the liquid to a jelly. This fact is some guarantee for the strength of the infusions. I took advantage of the clear weather this year to investigate the action of solar light on the development of life in these infusions, being prompted thereto by the interesting observations brought before the Royal Society by Dr. Downs and Mr. Blunt in 1877. The sealed ends of the flasks being broken off, they were infected in part by the water of an adjacent brook, and in part by an infusion well charged with organisms. Hung up in rows upon a board, half the flasks of each row were securely shaded from the sun, the other half being exposed to the light. In some cases, moreover, flasks were placed in a darkened room within the house, while their companions were exposed in the sunshine outside. The clear result of these experiments, of which a considerable number were made, is that by some constituent or constituents of the solar radiation an influence is exercised inimical to the development of the lowest infusoria. Twenty-four hours usually sufficed to cause the shaded flasks to pass from clearness to turbidity, while thrice this time left the exposed ones without sensible damage to their transparency. This result is not due to mere differences of temperature between the infusions. On many occasions the temperature of the exposed flasks was far more favourable to the development of life than that of the shaded ones. The energy which in the cases here referred to prevented putrefaction was energy in the radiant form. In no case have I found the flasks sterilised by insolation, for on removing the exposed ones from the open air to a warm kitchen they infallibly changed from clearness to turbidity. Four and twenty hours were in most cases sufficient to produce this change. Life is, therefore, prevented from developing itself in the infusions as long as they are exposed to the solar light, and the paralysis thus produced enables them to pass through the night-time without alteration. It is, however, a suspension, not a destruction, of the germinal power, for, as before stated, when placed in a warm room life was invariably developed. Had I had the requisite materials I should like to have determined by means of coloured media or otherwise the particular constituents of the solar radiation which are concerned in this result. The rays, moreover, which thus interfere with life must be absorbed by the liquid or by its germinal matter. It would therefore be interesting to ascertain whether, after transmission through a layer of any infusion, the radiation still possessed the power of arresting the development of life in the same infusion. It would also be interesting to examine how far insolation may be employed in the preservation of meat from putrefaction. I would not be understood to say that it is impossible to sterilise an infusion by insolation, but merely to indicate that I have thus far noticed no case of the kind.

The Sun-Spot Period and Planetary Tides in the Solar Atmosphere, by F. B. Edmonds.—The author said that the influence of the planet may be localised on a surface or stratum of small thickness, so that the disturbing force would vary as the square of the distance of the planet. Under this supposition the predominance of Jupiter seemed to shut out the idea that sun-spot maxima and minima could depend simply on the opposition and conjunction of the planets. The consequence of such a supposition was not to be lost sight of, but may be taken together with the more general supposition that the attractive force is exercised on a gaseous envelope, of which the altitude is not insignificant. Again, the mass of the sun is acted on by the planets, and such parts as are fluid, whether in the liquid or

gaseous form, are subject to a disturbance of a tidal character as a matter of course. The author argued that a disturbing body would therefore raise a tide on the sun more than one hundred times greater than the same force would raise it if acting on a globe the size of the earth, the other circumstances being the same. Looking at the sun-spot numbers as a record of spring tides and as a first approximation, recognising only such tides as would be due to the conjunction and opposition of Venus and the earth, it remained to establish a relation between these tides and the tide due to Jupiter in the form of special tides varying in magnitude with the sun-spot numbers.

On a New Integrating Anemometer, by H. S. Hele Shaw and Dr. Wilson.—An ordinary Robinson's cup anemometer is used to drive a train of wheels and thus ultimately a serrated roller, which moves a board in the direction of, and with a velocity proportional to, that of the wind. On the board, which is horizontal and about two feet square, is placed a sheet of paper, upon which the roller presses, and in turning leaves the required trace, at the same time moving the paper underneath it. The board is prevented from having a rotary motion by means of a pair of frames, the upper moving by means of wheels on the lower, each of which can only move in one direction, and these directions are perpendicular to each other. By a clockwork adjustment the time element is able to be introduced, which, taken in connection with space, gives velocity. A method of performing this was shown, as also a proposed form of the instrument for observatories.

On a Universal Sunshine Recorder, by G. M. Whipple.—The author gave a description of a new form of card-supporter for the Campbell sunshine recorder. It consisted of a light frame capable of holding the slip of cardboard, to be burned by the sun in any position. It was arranged so as to receive ordinary parallel strips of card at all times of the year, and to allow of the instrument being employed on any part of the earth's surface without detriment to its efficiency. The card-holders themselves are movable, so as to permit of the cards being changed indoors or dried, if wet, before removal, in order to avoid mutilating the record of the observation. The instrument also has an appliance for placing the card correctly in position to receive the sun's image.

On the Calibration of Mercurial Thermometers by Bessel's Method, by Prof. Rucker.—The author stated that the late Mr. Welsh of Kew Observatory described to the British Association in 1853 the methods which he introduced of making and correcting mercurial thermometers. The correction with which the author dealt was that due to the variations in the bore of the tube. Mr. Welsh's method of making this correction, which is still employed at Kew, is less theoretically perfect than others, and has been unfavourably criticised abroad. The author, in conjunction with Prof. Thorpe, has recently corrected a number of thermometers with great care by Bessel's method, which is the most elaborate and perfect hitherto proposed. One set of three thermometers were made for them at Kew, and were calibrated according to Welsh's method. Afterwards the measurements necessary for the application of Bessel's method were made by the Kew authorities, the calculations being performed by the author and Prof. Thorpe. The Kew thermometers were thus subjected to the most rigorous possible test, and they were able to announce that in one instrument the errors left after the application of Welsh's method were not greater than four-thousandths of a degree Centigrade, and in no case did they exceed one hundredth of a degree. As it is impossible to read on these thermometers less than a hundredth of a degree with certainty, Welsh's method, as applied at Kew, is practically perfect.

SECTION B—CHEMICAL SCIENCE

On a Process for Utilising Waste Products and Economising Fuel in the Extraction of Copper, by J. Dixon (Adelaide, South Australia).—This paper contains an account of a process for extracting copper from sulphurous ores, in which the heat generated by the combination of the oxygen of the air with the sulphur of the ore is utilised for the smelting of the ore. This process is based upon experiments, which, although the author regards as incomplete, show (1) that the charge grows visibly hotter by simply blowing air through it; (2) that the melting of the raw ore or regulus and its reduction can be carried on in the same furnace; (3) that if the ore is in lumps, and fed at the top whilst the air is admitted by the side, a practically clean slagg can be obtained; but if added in a coarse powder, as it is generally found in the market, it either blows out again or chokes the furnace; (4) that a rough copper of about 96 per cent. pure metal can be obtained by the successful working of this process.

On the Chemical Action between Solids, by Prof. Thorpe, Ph.D., F.R.S.—The author drew attention to the extremely rare instances of such action hitherto observed, showing how many of these might be explained on the supposition that combination actually occurred between the bodies either in solution or in a state of gas. For example, the formation of cement steel, by the combination of carbon with iron, which had long been adduced as an example of such combination between solids, was now explained by the fact that iron at a high temperature was permeable to gases, and that in the actual process of cementation oxides of carbon were formed, which were in reality conveyors of carbon to the metal. He then illustrated by experiments the formation of several compounds by bringing together the components in solid form, choosing as examples such as would manifest their formation by characteristic colouring. Thus, as instances, potassium iodide and mercuric chloride, potassium iodide and lead nitrate, and silver nitrate and potassium chromate, were powdered together in a mortar, and in each case evidence of an action was exhibited by the production of characteristic colours of the product of the reaction of these compounds. The author referred to the memoir of the Belgian physicist, Prof. Spring, on the same subject, some of whose experiments he had repeated and in the main confirmed. One of the most remarkable results obtained by the Belgian professor was the formation of coal from peat by subjecting the latter material to a high pressure. Peat from Holland and Belgium, when exposed to a pressure of about 6000 atmospheres, was, according to Spring, changed into a mass which in all physical characters resembled ordinary coal. Experiments of the same nature made by Dr. Thorpe with various samples of British peat yielded, however, a very dissimilar result. These experiments were made with pressures which were considerably less and more than those employed by Spring. Although solid, compact masses, hard and very much changed in structure, were attained, in no case was any product obtained which could be confounded with bituminous coal. He said it was highly improbable, on purely chemical grounds, that mere pressure had been little more than an important factor in the transformation of woody matter into coal.

Metallic Compounds containing Bivalent Hydrocarbon Radicals, Part ii., by J. Sakurai.—This is a continuation of the work, an account of which was given at the last meeting (NATURE, vol. xxii. p. 448, or *British Association Report*, 1880). *Dimercury methylene iodide*, $CH_2(HgI)_2$, is obtained by exposing methylene iodide with an excess of mercury to the action of light. It is a yellowish crystalline powder insoluble in ordinary solvents, but soluble in hot methylene iodide; it melts at 230° with partial decomposition. Iodine converts this compound into methylene iodine and mercuric iodide. This same compound is easily obtained by the exposure of the mono-mercuro-compound described last year (*loc. cit.*), mixed with mercury and mercuric iodide, to the sunlight. Hydric chloride reacts on dimercury methylene iodide, producing mercury iodomethide. The insoluble compound mentioned in the former publications (*loc. cit.*) the author regards $CH(HgI)_3$, and therefore contains a trivalent hydrocarbon radical. We have thus the following series of organo-mercury compounds:—

$$CH_3(HgI),\ CH_2(HgI)_2,\ CH_2HgI_2,\ \text{and}\ CH(HgI)_3.$$

On the Occlusion of Gaseous Matter by Fused Silicates at High Temperatures, and its Possible Connection with Volcanic Agency, by I. Lowthian Bell, F.R.S.

On the Siliceous and other Hot Springs in the Volcanic District of the North Island of New Zealand (with Photographic Illustrations), by W. Lant Carpenter, B.A., B.Sc., F.C.S. The author gives an account of his visit to this district in December, 1880; analyses of the water of many of the springs in the district are also given. The water of the springs in the neighbourhood of Lake Taupo were found to be chiefly siliceous; they are all more or less impregnated with free iodine, and possess a medicinal value. The water of one spring was found to be strongly impregnated with sulphates of iron and alumina. The water of the springs in the Hot Lake district of Rotona and Rotomahana contain large quantities of silica; the deposits from two of these form large siliceous terraces. The water of the springs in the White Island, which is the summit of an extinct volcano,

contains free hydrochloric acid in large quantities. The water of these springs deposits sulphur and sulphate of lime.

On the Two First Lines of Mendeleeff's Table of Atomic Weights, by W. Weldon, F.R.S.E. The author draws attention to certain relations exhibited by the fourth and eighth powers of the atomic weights of the elements in these two lines of Mendeleeff's series. The atomic weights used to exhibit these relations differ but slightly from those generally accepted. The fourth powers of the atomic weights of the elements from lithium to fluorine, viz. lithium, beryllium, boron, carbon, nitrogen, oxygen, and fluorine, are, with the exception of carbon, related to one another as the whole numbers 1, 3, 6, 16, 27, and 54. In order to establish a similar relationship for the atomic weight of all these elements, it is necessary to raise their atomic weights to the eighth power; when the following relationship is found to exist:—

$$\begin{aligned} Li^8 &= 1N^8 = 2^8 \\ G^8 &= 3^8 \qquad O^8 = 3^6 \\ B^8 &= 3^2 \times 2^8 \qquad F^8 = 3^6 \times 2^2 \\ C^8 &= 3^2 \times 2^3 \end{aligned}$$

Similar relationships are established for the fourth powers of the atomic weights of the elements in the next line of Mendeleeff's table. The author concludes that, in the case of each of these fourteen elements some power of their atomic weight is a simple multiple of the corresponding power of the atomic weight of lithium; further, that this multiple is a function of 2 or 3, or of 2 and 3 combined.

Note on the Chrome Iron Ore of Japan, by E. Divers, M.D.—This paper contains a description and analysis of a specimen of chrome iron ore found in serpentine rocks, in the prefecture Oita. Analysis shows it to contain magnesia, replacing ferrous oxide, and the formula $MgO_2FeO.2Cr_2O_3$ is attributed to it.

On the Oxides of Manganese, by V. H. Veley, B.A.—The author at the outset gives an historical sketch of the researches on this subject, in order to show how far it has been satisfactorily proved by them—(1) that manganese forms a series of definite oxides (apart from those present in manganic and permanganic acids); (2) that manganese dioxide forms a series of dioxides. An account is also given of the researches of Dittmar, Wright, and others on the conditions of formations of these oxides, and their behaviour when heated to various temperatures in certain gases. The author has studied the action of air, oxygen, nitrogen, and hydrogen at temperatures varying from 60°–200°, on an oxide having the formula Mn_8O_{11}. Hydrates of the following higher oxides, $Mn_{24}O_{32}$, $Mn_{24}O_{44}$, $Mn_{24}O_{45}$, $Mn_{24}O_{46}$, $Mn_{24}O_{47}$, have been prepared and analysed. When these oxides are heated in air or oxygen, at low temperatures, two changes are observed: (1) a loss of water of hydration; (2) an absorption of oxygen. When heated in nitrogen they are dehydrated, and at higher temperatures lose available oxygen. Heated in hydrogen, they are simultaneously dehydrated and reduced. The author regards these oxides as distinct chemical entities, and not mere combinations of molecules, or molecular compounds.

On the Inferences deducible from High Molecular Weights as exhibited by the Oxides of Manganese, by Prof. Odling, M.B., F.R.S.—In the course of his remarks Prof. Odling brought under the notice of the Section the various considerations which affected the determination of the relative weights of the reacting units of chemical substances. He contended that estimations of vapour-density had not had, and could not have, an absolutely determining influence, but thought these estimations always required to be checked by purely chemical considerations. In particular he referred to the cases of bodies which had two or more distinct vapour-densities—cases which were becoming added to daily. He expressed his entire concurrence with the views of the President of the Section as to the non existence of two distinct forms of combination, atomic and molecular, and strongly opposed the notion that various metallic elements possessed a definite capacity of saturation. He brought forward various illustrations to show that the saturation capacity of both metallic and non-metallic elements was indefinite. He contended that the doctrine of atomicity furnished a very inadequate idea of the most important facts of chemical combination, and that the representation of atomicity notions by graphic formulæ was highly misleading.

On Peppermint Camphor (Menthol) and some of its Derivatives, by R. W. Atkinson, B.Sc. (Lond.), and H. Yoshida.—This paper contains an account of the determinations of the physical properties of menthol ($C_{10}H_{20}O$), menthone ($C_{10}H_{18}O$), menhene ($C_{10}H_{18}$), and those of a hydrocarbon, $C_{10}H_{16}$, which latter compound is obtained by the action of hydric iodide upon menthol and subsequent treatment with caustic soda and metallic sodium. The authors also discuss the constitution of the above compounds.

Note on the Occurrence of Selenium and Tellurium in Japan, by E. Divers, M.D.—The author draws attention to the fact that the presence of these two elements has been observed in Japanese sulphuric acid, and considers it probable that these substances occur in material quantities in Japan.

Note on the Sodium Alum of Japan, by E. Divers, M.D.—An analysis is given of a specimen of this substance; it occurs as an efflorescence on decomposing sodium albite, which contains pyrites scattered through it. It is found in the province of Idzumo, in the prefecture of Shiniané, near the coast. It is said to occur in considerable quantities. It occurs in two forms, one massive, finely fibrous, greyish white and translucent, and the second in friable opaque tears, slightly coloured by iron oxide.

Brewing in Japan, by R. W. Atkinson, B.Sc. (Lond.).—The Japanese brewing process is divided into two parts comparable with the malting and brewing processes of beer-making. The mode of preparation and the properties of the diastatic materials are different in the two cases. The Japanese equivalent of malt or "köji" hydrates maltose in addition to cane-sugar, dextrin, and starch, and the ultimate products of its action on starch-paste are dextrose and dextrin, or perhaps dextrose alone. Köji differs from malt in being rendered inactive by heat at a much lower temperature than malt. Köji is prepared as follows: a mixture of steamed rice and water is allowed to remain in shallow tubs at a low temperature (0°–5° C.) until quite liquid; it is then heated, fermentation commences, and continues until nearly all the dextrine first formed is exhausted. This product is now used like yeast, and is added to fresh quantities of steamed rice and water, fermentation proceeding until the percentage of alcohol amounts to about 13 or 14 per cent. by weight. After the greater part of the rice added has been used up, the mash is filtered and clarified by standing. The "saké" so produced requires very careful watching, and when summer approaches, or it exhibits signs of putrefactive fermentation, it is then heated in iron vessels; this operation has frequently to be repeated. Analyses of various specimens, fresh and diseased, are given in the paper.

Observations on the Specific Refraction and Dispersion of Light by Liquids, by J. H. Gladstone, Ph.D., F.R.S.—The general conclusions arrived at from a large series of observations on different liquids are as follows:—

I. The confirmation of the statement made by the Rev. T. P. Dale and the author, viz., that the length of the spectrum (the difference between the refraction of the Fraunhofer lines A and H) decreases with elevation of temperature.

II. It would appear that the length of the spectrum divided by the density, *i.e.*, $\frac{\mu H - \mu A}{d}$, is approximately, but not exactly, constant for different temperatures.

III. The specific dispersion appears to decrease with increase of temperature.

IV. The specific dispersion is influenced by the chemical constitution of a compound. In the case of hydrocarbons the change of the refractive equivalent of the carbon from 5·0 to 6·1 or 8 influences the specific dispersion to a far greater extent than the specific refraction.

V. Finally, the specific dispersion of a compound does not appear to be the means of the specific dispersions of its constituents.

On the Production of Crystals by the Action of Metals on Carbon Disulphide in Sealed Tubes, by P. Braham, F.C.S.—The author described a series of experiments which consisted in sealing up fifteen different metals in carbon disulphide. Some of these tubes were sealed up in 1879, and in those which contained gold, antimony, and bismuth, microscopic crystals were found. The composition of these crystals has not as yet been determined. The author also exhibited a micro-goniometer.

On the Alleged Decomposition of the Elements, by Prof. Dewar, M.A., F.R.S.—In his remarks Prof. Dewar dealt chiefly with the spectroscopic work from which Mr. Norman Lockyer had drawn conclusions very different from those of Professors Liveing and Dewar, especially concerning the value of evidence on the subject. Prof. Dewar argued that Mr. Lockyer's views regarding the existence of carbon vapour in the corona of the sun would not bear scientific investigation, and that his views regarding the modifica-

tion of the spectrum of magnesium were equally illusory, and gave no proof of the decomposition of elementary substances. Finally he discussed Mr. Lockyer's theory of "basic lines," and addressed himself to a refutation of the same. The results recorded, he said, strongly confirmed Young's observations, and left little doubt that the few as yet unresolved coincidences either would yield to a higher dispersion, or were merely accidental. It would indeed be strange if amongst all the variety of chemical elements and the still greater variety of vibrations which some of them were capable of taking up, there were no two which could take up vibrations of the same period. They certainly should have supposed that substances like iron and titanium, with such a large number of lines, must each consist of more than one kind of molecule, and that not single lines, but several lines of each, would be found repeated with the spectra of some other chemical elements. The fact that hardly a single coincidence could be established was a strong argument that the materials of iron and titanium, even if they be not homogeneous, were still different from those of other chemical elements. The supposition that the different elements might be resolved into simple constituents and even into a single substance had long been a favourite speculation with chemists; but however probable that hypothesis might appear *à priori*, it must be acknowledged, according to Prof. Dewar, that the facts derived from the most powerful method of analytical investigation yet devised, gave it but scant support.

On Manganese Nodules and their Occurrence on the Sea-Bottom, by J. Y. Buchanan.—The author exhibited specimens of the nodules obtained from the South Pacific, and also from Loch Fyne; an account of those obtained in Loch Fyne was given in NATURE, vol. xviii. p. 628. Some nodules containing cobalt were also exhibited; these the author had obtained from New Caledonia. An account is given of the author's method of dredging for mud. The nodules have been found to contain iron oxides, copper, cobalt, nickel, sand, &c. Further, in no case was the amount of oxygen found to be sufficient to form a peroxide with the manganese. The kernels of these nodules are usually richer in manganese oxides than the external portions. Concerning their mode of formation the author thinks that this takes place *in situ*, and that the nodules are not brought from a distance. Further, it would appear that living organisms assist in this formation, although indirectly, inasmuch as the decomposing animal matter reduces the sulphates of the sea-water to sulphides, which in their turn react on the iron and manganese minerals (chiefly silicates) in the mud, and thus forming sulphides of these metals. When the organic matter is exhausted these sulphides are oxidised to oxides by the oxygen of the water, forming concretions or incrustations of the ochreous oxides, which naturally inclose the other and unaltered constituents of the mud.

On the Action of Zinc, Magnesium, and Iron on Acidified Solutions of Ferric Sulphate, by Prof. T. E. Thorpe, Ph.D., F.R.S.—The extent of the reduction of the ferric salt may vary with the strength of the solution, with its temperature, with the amount of free acid present, and lastly with the specific nature of the metal employed. The author has studied the conditions under which the hydrogen does work as a reducing agent. Experiments were made on dilute solutions of ferric sulphate, containing known quantities of free acid. The author finds (1) that the extent of reduction, produced by a given weight of zinc in dissolving, increases with the temperature; (2) that it is also affected, although to a less degree, by the initial surface of the metal exposed. Whilst the extent of reduction, as also the rapidity of solution, increase with the temperature, at a given temperature the extent of reduction increases, although at a gradually diminishing rate, with the time of solution. The rapidity of solution and extent of reduction produced by a given quantity of zinc, of a given area and in a solution of a given temperature, and containing a definite weight of free acid, increase with the amount of reducible iron present. Experiments made by placing zinc in contact with platinum showed that, although the time of solution of zinc in contact with platinum is considerably diminished, as compared with that of zinc alone, little difference in the reducing effect is observed. Similar results were obtained with magnesium, although the amount of reduction is from one-fourth to one-third of that produced by zinc under similar conditions. The diminution of the rate of solution with decrease in the amount of free acid present, is far greater in the case of magnesium than in that of zinc. The author concludes that his experiments strongly support the view that the reducing power of nascent hydrogen is connected with the existence of this body in the atomic condition, since all conditions tending to prolong the duration of this atomic condition augment the reducing power.

On the Reducing Action of Zinc and Magnesium on Vanadium Solutions, by Prof. Roscoe, LL.D., F.R.S.—From his original experiments on this subject the author had drawn the conclusion that, whilst the reduction in the case of zinc and sodium took place from V_2O_5 to V_2O_2, in the case of magnesium it only proceeded to V_2O_3. Later experiments have, however, shown that each of these reducing agents acts in the same manner, but that the reduction from V_2O_5 to V_2O_2 takes place very slowly when magnesium is used.

Note on a New Method of Measuring Certain Chemical Affinities, by A. Tribe.—The author points out that when a metal is immersed in an electrolytic field, *i.e.*, in an electrolyte in the act of electrolysis, and the electromotive force set up on any part of its surface is sufficient to decompose the medium, then the positive *ion* separates out on that part of the surface which has received negative electrification, and the negative *ion* on the portion which is positively electrified. If such a plate be of a rectangular form, and it be so placed that the lines of force are perpendicular to its surface, then the maximum electromotive force is set up in the central part of the plate, and at the edges it becomes so weak as to be unable to initiate any electro-chemical action. If the sheet be placed in the electrolytic field, so that the lines of force are parallel with its sides and with two of its edges, then the maximum electromotive force is at the end of the plate and is the weakest at the centre, where it is unable to bring about electro-chemical changes. That this is the case is shown by the boundaries of the deposits, which in many cases are very sharply defined. From the intimate connection between electromotive force and chemical affinity, the author supposed that if, in a series of trials, the chemical affinities were altered, other circumstances remaining the same, the magnitude of the intermedial space between the boundaries of the electro deposits would increase with the force required to overcome the affinities of the *ions* of the electrolytes. This supposition has been confirmed by several experiments, *e.g.*, with sheets or analysers of silver immersed in solutions of chloride, bromide, and iodide of zinc, it was found that the intermedial space was the greatest in the case of the chloride, and in the case of the bromide it was greater than in the case of the iodide.

On some Phenomena of the Nature of Chemico-Magnetic Action, by W. Thomson, F.R.S.E.—The author had observed that the colour from a piece of cloth dyed with Prussian blue was discharged in the neighbourhood of a piece of iron which had been lying upon it for some weeks. The ash of the portions of cloth from which the colour had been discharged was found to contain but a trace of iron. Experiments were made in which no iron was used, and the blue colour was bleached but slightly, showing that the action could not be attributed to light alone. Further experiments, in which small pieces of iron or magnets were used, showed not only that the colour was discharged, but that the colour so discharged appeared to be rearranged in semicircles on each side of the bar of iron. When magnets were used, the colour assumed more or less of circular forms, which were developed not only from the poles, but from all parts of the magnets. These phenomena the author does not regard as due to magnetic action, for when a piece of gutta percha tissue was placed between the wet cloth and the magnet, no action took place, even after several weeks. Similar observations have been made with cloth dyed with aniline colours, and with a like result.

On the Double Iodide of Copper and Mercury, by Prof. Silvanus P. Thompson, D.Sc.—After describing the preparation of this compound, which is cuproso-mercuric iodide, Cu_2HgI_4, the author draws attention to one property, viz., its change of colour by a comparatively small change of temperature. At the ordinary temperature this substance possesses a brilliant red colour, and when heated, it becomes black, changing back to red on cooling. In thin layers this substance transmits light, but becomes opaque on heating. Now according to the electro-magnetic theory of light, opaque bodies are the best conductors of electricity; therefore this double iodide of copper and mercury should conduct heat better at a high than at a low temperature. Experiment has shown this to be true to a certain extent only, as beyond a certain temperature its conductivity becomes less; this is probably due to its decomposition when heated beyond a given temperature. In conclusion, the author pointed out several ways in which this change of colour of this

compound could be used in lecture experiments. For instance, it may be used to show the conduction of heat along a copper rod; for this purpose the rod is coated with the red compound, which is gradually blackened as the heat travels along the rod. It may also be substituted for wax in Tyndall's experiment for showing how crystals conduct heat. There are also a variety of other ways in which it may be applied.

The Effect of the Spectrum on Silver Chloride, by Capt. Abney, R.E., F.R.S.

Alterations in the Properties of Nitric Ferments by Cultivation, by R. Warington.—The author, after giving an account of his experiments on the cultivation of these ferments, which consist of organisms resembling bacteria, states that these nitrifying ferments are capable of existing in three forms—(1) the nitric ferment of soil, which converts both ammonium salts and nitrites into nitrates; (2) the altered ferment, which converts ammonium salts into nitrites, but fails to convert nitrites into nitrates; (3) a surface organism which converts nitrites into nitrates.

On the Fluid Density of Certain Metals, by Prof. W. Chandler Roberts, F.R.S., and T. Wrightson, C.E.—This is an account of a continuation of experiments upon this subject, some of which were submitted to the Section at Swansea (*vide* NATURE, vol. xxii. p. 448). The authors also exhibited the *oncosimeter* described in the *Journal* of the Iron and Steel Institute (ii. 1879, p. 418), by the aid of which these results were obtained. The following table contains the results obtained:—

	Sp. gr. solid.	Sp. gr. liquid.	Percentage of change in volume.
Bismuth	9·82 ...	10·055 ...	Decrease 2·3
Copper	8·8 ...	8·217 ...	Increase 7·1
Lead	11·4 ...	10·37 ...	,, 9·93
Tin	7·5 ...	7·025 ...	,, 6·76
Zinc	7·2 ...	6·48 ...	,, 11·10
Silver...	10·57 ...	9·51 ...	,, 11·2
Iron	6·95 ...	6·88 ...	,, 1·02

On Molecular Attraction, by F. D. Brown, B.Sc.—The author points out that, if we regard chemical affinity as neutralised by the union of two elements, we are then unable to account for the reactions taking place between molecules, and involving an interaction of the atoms composing different molecules. If, however, the act of combination be regarded as producing no change in the chemical forces, and it be supposed that the same attraction is exerted between any given pair of atoms without regard to the state of combination of one or both of the atoms, then a reasonable account can be given of chemical reactions, and the existence of molecular combinations does not appear very remarkable. Further, we are provided with a more or less effective explanation of the relative volatility of substances. Reasoning from this point of view, and considering the carbon compounds specially, the author concludes that intermolecular attraction should be greater in an acid than in a corresponding alcohol; greater in an alcohol of high molecular weight than in a homologue of which the molecule is less complex; greater in a primary alcohol than in the secondary or tertiary isomeride; and finally, greater in a chlorinated compound than in the corresponding substance containing hydrogen. If the volatility of a substance be a measure of the forces of attraction between the molecules, then it must be admitted that the boiling points of organic compounds show with some reason that the above expression represents the value of intermolecular attraction. From this point of view the study of the latent heat of many carbon compounds would materially aid us in the solution of the problem of chemical affinity.

On the Relative Atomic Weights of Silver, Manganese, and Oxygen, by Prof. Dewar, M.A., F.R.S., and A. Scott, B.A., B.Sc. The authors have determined the atomic weight of manganese, in relation to silver and oxygen, by a complete analysis of silver permanganate. Taking the atomic weight of silver to be 108, that of oxygen to be 16, the following values have been obtained for the atomic weight of manganese, 55·51, 54·04, 54·45. These numbers do not agree very well amongst themselves, nor with the numbers obtained from the analysis of pure manganese peroxide, made from manganese nitrate. By this latter method the following values were obtained, viz., Mn = 53·6 and 53·3.

Note on the Phosphates of Lime and Ammonia, by J. Alfred Wanklyn.—When ammonia is added to a soluble calcic phosphate a precipitate is obtained, which dissolves on heating, forming a viscid solution which solidifies on cooling. The soluble salt formed the author regards as having the composition $P_2O_5CaO(NH_4)_2OH_2O$. The author confirms Morfit's observation, that bone earth dissolved in acid is reprecipitated by alkalies in the form of a hydrated tribasic phosphate; a fact which he considers of great importance to agriculture.

On the Separation of Hydrocarbon Oil from Fat Oils, by A. H. Allen, F.C.S.—The author pointed out that the extensive production of hydrocarbon oils and their cheapness had led to their being employed for the purpose of adulterating animal and vegetable oils. Indications of their presence are afforded by the determination of the density of the oil, by the lowering of its flashing point and boiling point, further by its taste and the odour produced on heating. An oil so adulterated is not completely saponified, and the hydrocarbon oil may be removed from the product of saponification by extraction with ether. Fluorescence is also to some extent a useful indication of the presence of such a mineral oil; the fluorescence of some mineral oils may, however, be destroyed by chemical means, and as some mineral oils are not fluorescent the absence of fluorescence in an oil does not therefore indicate the absence of a mineral oil.

On Bowkett's New Thermograph, by W. Lant Carpenter, B.A., B.Sc., F.C.S.—This is an instrument for recording changes of temperature, which are measured by the action of heat upon a hollow circular metallic ring connected with a circular vessel, the whole being filled with fluid and hermetically sealed. One end of the ring is fixed, the other is free to move, and its motion is magnified by a series of levers, to the end of which is attached a recording pen. Increments of heat cause increments of pressure in the ring, which moves at its free end. The instrument has hitherto been used for clinical purposes only, but the author thinks it might with advantage be used in chemical and physical researches.

The Blowing Wells near Northallerton, by T. Fairley, F.R.S.E.—The author gave an account of a series of observations on these wells, of which there are three in the neighbourhood of Northallerton. The gas issuing from the fissures in these wells has been analysed, and is apparently nothing more than common air.

On the New Metal Actinium, by J. L. Phipson.—The author stated that he had been able to separate a new element from the pigment zinc-white. The oxide of the new element is said to be slightly soluble in caustic soda, and is soluble in ammonia and ammoniacal salts. Its colour is uninfluenced by exposure to light. The sulphide of actinium is described as a pale yellow canary-coloured substance; it is insoluble in ammonium sulphide, is soluble in acetic acid, and becomes darker on exposure to the air.

On some Vapour-Density Determinations, by Prof. Dewar, M.A., F.R.S., and A. Scott, B.A., B.Sc.—The authors described the apparatus they employed for the determination of the vapour-densities at high temperatures, and the means adopted for examining the vapours to ascertain whether or not decomposition had taken place. The vapour-densities of the halogen compounds of several metals have been determined, and it is interesting to note that the authors find, according to its vapour-density, the molecular formula for ferrous chloride is $FeCl_2$.

Some Remarks on Crystallogeny, by Prof. J. P. Cooke (Harvard University, U.S.A.).

On a New System of Blow-pipe Analysis, by Lieut.-Col. Ross.—The author described his system of blow-pipe analysis, and exhibited a compact form of blow-pipe and other necessary apparatus for use when travelling.

On Experiments with Manures on Barley Crops, Season 1881, by Ivison Macadam, F.C.S.—The author gave a detailed account of his experiments on two fields sown with barley in April of this year. The previous rotation of crops was as follows:—in 1878 potatoes with 20 tons of farmyard manure per acre, and 4 to 5 cwt. of dissolved manure; in 1879 wheat, no manure; in 1880 turnips, 20 tons per acre of town ashes and 5 to 6 cwt. of dissolved manure. The only difference between the two fields was that in one case the turnips were carted away, whilst in the other they were eaten on the ground by sheep. From the time when the barley appeared to the time of cutting, determinations of the following points were made every week: (1) the weight of the plant; (2) length of straw; (3) rate of storage of saline matter by the plant; (4) amount of water, nitrogen (given as ammonia), organic and vegetal matter; (5) the amount of the various saline ingredients present in the ash. The results appear to show that, in the case of the field where the turnips had been eaten on the ground, the barley crop grew more rapidly and was more healthy than that on the other field.

SECTION C—GEOLOGY

On the Laurentian Beds of Donegal and of other Parts of Ireland, by Prof. Edward Hull, LL.D., F.R.S., &c., Director of the Geological Survey of Ireland.—After a perusal of the writings of previous authors, and a personal examination made in the spring of 1881, in company with two of his colleagues of the Geological Survey, Mr. R. G. Symes, F.G.S., and Mr. S. B. Wilkinson, the author had arrived at the following conclusions:—1. That the Gneissose series of Donegal, sometimes called "Donegal granite," is unconformably overlaid by the metamorphosed quartzites, schists, and limestones which Prof. Harkness had shown to be the representatives of the Lower Silurian beds of Scotland (*Quart. Journ. Geol. Soc.*, vol. xvii. p. 256). This unconformity is especially noticeable in the district of Lough Salt near Glen. 2. That the Gneissose series is similar in character and identical in position and age with the "Fundamental Gneiss" (Murchison) of parts of Sutherlandshire and Ross-shire, and is therefore, like the latter, presumably of Laurentian age. That the formation is a metamorphosed series of sedimentary beds, has been shown by Dr. Haughton and Mr. R. H. Scott. 3. That the north-western boundary of the Donegal gneiss is a large fault between the Laurentian gneiss and the metamorphosed Lower Silurian beds, owing to which the older rocks have been elevated, and by denudation have been exposed at the surface. 4. That the Cambrian formation of Scotland is not represented in Donegal, and that the unconformity above referred to represents a double hiatus, and is of the same character as that which occurs in Sutherlandshire, in the district of Fornaven and Ben Arkle, where the Lower Silurian beds rest directly on the Laurentian gneiss. 5. That Laurentian rocks may be recognised in other parts of Ireland, as in the Slieve Gamph and Ox Mountains of Mayo and Sligo, at Belmullet, and in West Galway, north of Galway Bay, where the rocks consist of red gneiss, hornblende rock, and schist, &c., similar to those in Donegal; also possibly in Co. Tyrone, as suggested by Mr. Kinahan.

Laurentian Rocks in Ireland, by G. H. Kinahan, M.R.I.A., &c.—The writer first mentioned that Cainozoic and Mesozoic rocks only occurred in the province of Ulster, while in the rest of the island there was a nearly continuous sequence of Palæozoic rocks, proved by the work of Griffith, Jukes, and their subordinates, from the Coal-Measures down to the Cambrian. He then pointed out that a recent attempt had been made to try and disturb their natural order, but that the new theory was solely founded on assertions that would not bear investigation. He proceeded to observe that the geologists of the pre-Cambrian school appeared to lay more weight on lithological evidence than that to which it was entitled, and in continuation he gave the localities for the oldest rocks in Ireland, with the reasons for and against the rocks being Laurentian. The localities are *Carngore*, or South-East Wexford, while it was shown that although the rocks were lithologically similar to the Laurentians, yet they contained Cambrian fossils—*Galway, South-East Mayo, Sligo, and Leitrim*—rocks that, from their lithological characters, were said to be Laurentian by Murchison, who recanted his statement when Harkness showed that stratigraphically this was an impossibility. These rocks occur on two zones, those on the highest being now said to be Laurentian—*Erris, North-West Mayo*—very old rocks, about which nothing can be positively said, except that they are older than the associated metamorphic rocks, also of uncertain age. *Donegal, Londonderry, and Tyrone*—the Laurentian age of some of these, years ago, was suggested by Jukes, while now it is positively asserted, but solely on lithological characters. The author pointed out that, although lithologically very like Laurentians, they were more like Huronians, Logan's description of the latter being very suitable for those of Donegal. He also pointed out that it was unnecessary to make vague assertions, as the stratigraphical position of the rocks ought to be easily worked out, either by starting from the Pomeroy fossiliferous rocks, or from the fossiliferous rocks found in Donegal by Dr. King; but that, at the same time, the work must be much better and more correctly done than that in the neighbourhood of Pomeroy, where the unaltered fossiliferous beds are classed with those they lie on, although the latter were extensively metamorphosed, contorted, upturned, and denuded, prior to the fossiliferous rocks being deposited on them. *North-East Antrim*-rocks, supposed to be of the same age as the older rocks near Pomeroy (*Upper Cambrians*).

On the Occurrence of Granite in situ about Twenty Miles South-West of Eddystone, by A. R. Hunt, M.A., F.G.S.—The author described and exhibited a fragment of granite brought up by a Brixham trawler twenty miles south-west of the Eddystone. He believed it to have been torn off a mass of granite *in situ*, and pointed out that in mineral composition it agreed with the gneisses of the Eddystone Reef and of the Shovel Reef in Plymouth Sound—all these rocks being composed of mica, quartz, and felspar, without hornblende or schorl. The author believed that the occurrence of gneiss in Plymouth Sound without altering the adjacent Devonian rocks was an indication that these Channel typical gneisses, and probably the typical granites too, were of pre-Devonian age.

Some Observations on the Causes of Volcanic Action, by J. Prestwich, M.A., F.R.S., &c., Professor of Geology in the University of Oxford.—The hypothesis generally accepted in this country as to the cause of volcanic action is that of the late Mr. Poulett Scrope, who considered that "the rise of lava in a volcanic vent is occasioned by the expansion of volumes of high-pressure steam, generated in a mass of liquefied and heated matter within or beneath the eruptive orifice," and that the expulsion of the lava is effected solely by high-pressure steam generated at great depths, but at what depths is not mentioned, nor is it explained how the water is introduced, whether from the surface, or whether from water in original combination with the basic magma. The objections to this hypothesis are—1. That during the most powerful explosions, *i.e.*, when the discharge of steam is at its maximum, the escape of lava is frequently at its minimum. 2. That streams of lava often flow with little disengagement of steam, and are generally greatest after the force of the first violent explosion is expended. 3. That it is not a mere boiling over, in which case, after the escape of the active agent—the water—and the expulsion of such portion of the obstructing medium, the lava, as became entangled with it, the remaining lava would subside in the vent to a depth corresponding to the quantity of lava ejected; but the level of the lava, *ceteris paribus*, remains the same during successive eruptions. Of the important part played by water in volcanic eruptions there can be no doubt, but instead of considering it as the primary, the author views it as secondary cause in volcanic eruptions. All agree in describing ordinary volcanic eruptions as generally accompanied or preceded by shocks or earthquakes of a minor or local character, to which succeed paroxysmal explosions, during which vast quantities of stones, scoriæ, and ashes, together with volumes of steam, are projected from the crater. The first paroxysms are the most violent, and they gradually decrease and then cease altogether. The flow of lava, on the other hand, which commences sooner or later after the first explosions, is continued and prolonged independently. Ultimately the volcano returns to a state of repose, which may last a few months or many years. Adopting the theory of an original igneous nucleus, the author considers a certain fluidity of the former, and mobility of the latter. The one and the other feebly represent conditions of which the phenomena of the rocks afford clearer and stronger evidence as we go back in geological time. Although thermometrical experiments, of the necessary accuracy and length of time, are yet wanting, it has been estimated that a small quantity of central heat still reaches the surface and is lost by radiation into space, and the escape of liquid lava and steam from volcanoes, and of hot springs from these and other sources, must bring, in however small a quantity, a certain increment of heat from the interior to the surface, where it is lost. This should lead to a certain contraction at depths, and of readjustment of the external crust, in consequence of which the fused masses of the interior will from time to time tend to be forced outwards, whenever tension became sufficient to overcome resistance. In this the author agrees with many other geologists. The further hypothesis respecting volcanic action, he now suggests, he has been mainly led to form by his researches on underground waters. A portion of the rain falling on the surface not only of permeable and fissured sedimentary strata, but also of fissured and creviced crystalline and other rocks, passes below ground, and is there transmitted as far down as the permeal le rocks range, or as the fissures in the rocks extend, unless some counteracting causes intervene. Those causes are the occurrence of impermeable rocks, faults, and heat. The former two are exceptional, the latter constant. The increase of temperature with depth being 1° Fahr. for every 50 to 60 feet, the boiling point of water would be reached at a depth of about 10,000 feet, but owing to the pressure of the superincumbent rocks, it has been estimated that water will retain its liquidity and continue

circulate freely to far greater depths. Unfortunately, very little is known of the substrata of volcanoes. Etna and Hecla apparently stand on permeable Tertiary strata, Vesuvius on Tertiary and Cretaceous strata, while in South America some of the volcanoes are seemingly situated amongst palæozoic and crystalline rocks. Under ordinary circumstances all the permeable strata and all fissured rocks become charged with water up to the level of the lowest point of escape on the surface, or if there should be an escape in the sea-bed, then to that level, *plus* a difference caused by friction. The extreme porosity of lavas is well known. All the water falling on the surface of Etna and Vesuvius (except where the rocks are decomposed and a surface soil formed) disappears at once, passing into the fissures and cavities formed by the contraction of the lava in cooling. Not only are these fissures filled, but the water lodges in the main duct itself, and occasionally rises to a height to fill the crater. Beneath the mass of fragmentary and cavernous volcanic materials forming the volcano, lies the original compact mass of sedimentary strata, &c. Owing to the fortunate circumstance of an Artesian well having been sunk at Naples, we know the underlying sedimentary strata there to consist of alternating strata of marl, sands, and sandstones, some water-bearing, others impermeable. The water from the lowest spring reached in this boring rose at first 8 feet above the surface, and 81 feet above the sea-level. Where the strata crop out in the sea-bed, the same pressure of the column of inland water forces the fresh water outwards, so as to form a freshwater spring in the sea, as at Spezzia and elsewhere on the Mediterranean coast. It is this fundamental hydrostatic principle which keeps wells in islands, and in shores adjacent to the sea, free from salt water, as in the Isle of Thanet. Where, however, the head of inland waters is small or impeded, sea-water will enter the permeable strata, and spoil the springs, as in the case of the Lower Tertiary sands at Ostend, and the Lower Greensand at Calais and in the Somme, in which latter department the underground spring was found affected to a distance of about one mile from the sea, but pure at a distance of nine miles. Further, if where the head of inland water is sufficient to force back the sea-water under ordinary conditions, those ordinary conditions are disturbed by pumping to an extent that lowers the line of water-level to below that of the sea-level, then the sea-water will flow inwards until an equilibrium is established. The flow of water under a volcanic mountain may be also influenced by the quaquaversal dip, which there is some evidence that the underlying strata there take, owing probably to the removal of matter from below, and the weight of the mountain. If we are to assume that the volcanic ashes and tufas below Naples are subaërial, the original land-surface has sunk not less than 665 feet, and a dip of the underlying strata from the seaward, as well as from inland, has in all probability been caused. This Artesian well was carried to the depth of 1524 feet, and passed through three water-bearing beds—one in the volcanic ashes, the second in the sub-Apennine beds, and the third in the Cretaceous strata at the bottom. No eruption of lava can then take place without coming in contact with these underground waters. The first to be affected will be the water in the cavities of the mountain in and around the crater. As the pressure of the ascending column of lava splits the crust formed subsequently to the preceding eruption, the water finds its way to the heated surface, and leads to explosions more or less violent. When the fluid lava breaks more completely through the old crust, and the mountain is fissured by the force and pressure of the ascending column, the whole body of water stored in the mountain successively flows in upon the heated lava, and is at once flushed off into steam. Then take place those more violent detonations and explosions—those deluges of rain arising from the condensed steam—with which the great eruptions usually commence. In conclusion, the author conceives that the first cause of volcanic action is the welling up of the lava in consequence of pressure due to slight contraction of a portion of the earth's crust. Secondly, the fluid lava coming into contact with water stored in the crevices of the masses of lava and ashes forming the volcano, the water is at once flushed into steam, giving rise to powerful detonations and explosions. Thirdly follows an influx of water from the underlying sedimentary or other strata lying at greater depths into the ducts of the volcano; and, lastly, as these subterranean bodies of water are thus converted into steam and expelled, the exhausted strata then serve as a channel to an influx of sea-water into the volcano. A point is finally reached when, owing to the cessation of the powerful shocks and vibrations, and the excessive drainage of the strata, the flow of the lava is effected quietly, and so continues until another equilibrium is established and the lava ceases to escape.

The Connection between the Intrusion of Volcanic Action, by Prof. W. J. Sollas, M.A.—In a volcanic eruption there are concerned first the elevation of the lava column in the axial pipe of the volcano, and next the explosion by which the lava is ejected into the air. The author attempts to find a *vera causa* for the latter. Sorby's researches on included cavities prove that steam at a high tension must have been everywhere present throughout plutonic rocks when these were in a state of fusion, and the presence of steam in ejected lava is well known. He considers it probable that the axial pipe of a volcano is occupied by fused rocks permeated by steam, which is probably in a liquid state, and the tension of which will depend on the hydrostatic pressure due to the lava column above it. Any sudden diminution of this pressure will tend to a sudden expansion of the steam, and tend to produce a volcanic explosion. The mere elevation of the lava in the volcanic pipe cannot directly produce a diminution of pressure, though an overflow at the surface of the ground would, but this infers that the overflow of lava should precede an eruption, which is not the case; hence the author concludes that an overflow of lava from the sides of the pipe and other places underground, and the pressure on the lava column being reduced beneath the point of overflow, an eruption follows. The ascendant pressure of intruded sheets and dykes of igneous rock known to occur beneath volcanic cones thus stands in close connection with the production of volcanic explosions.

A Restoration of the Skeleton of Archæopteryx, with some Remarks on Differences between the Berlin and London Specimens.—Prof. H. G. Seeley, F.R.S., traced the forms of the bones from a photograph, and arranged the skeleton so as to represent a bird which stood about ten inches high. The head has a post-occipital process in the cormorants; the neck is curved forward; the tail reached almost to the ground; and the limbs were exactly as in birds.

On Simosaurus pusillus (Fraas), *a Step in the Evolution of the Plesiosauria.*—Prof. H. G. Seeley gave a detailed description of the skeleton of Simosaurus recently discovered in the Trias near Stuttgart, and briefly noticed and figured by Dr. Oscar Fraas. He then drew special attention to the difference from Plesiosaurus, especially in the form of the pectoral arch and in the characters of the fore and hind limbs. The hind limb was discussed, to show how it might assume like character with the fore limb. Prof. Seeley concluded that the Plesiosaurus were originally land animals, and that their ancestors and affinities must be sought in Simosaurus, Nottosaurus, and allied types of amphibious Triassic reptiles.

Influence of Barometric Pressure on the Discharge of Water from Springs, by Baldwin Latham, M.Inst.C.E.—The author of this paper mentioned that it was alleged, by some of the long-established millers on the chalk streams, that they were able to foretell the appearance of rainfall from a sensible increase in the volume of water flowing down the stream before the period of rainfall. He had, therefore, undertaken a series of observations to investigate the phenomena, and he found, in setting up gauges in the Bourne flow in the Caterham Valley, near Croydon, in the spring of this year (1881), and selecting periods when there was no rain to vitiate the results, that whenever there was a rapid fall in the barometer, there was a corresponding increase in the volume of water flowing, and with a rise of the barometer, there was a diminution in the flow. The gaugings of deep wells also confirmed these observations; for where there was a large amount of water held by capillarity in the strata above the water-line, at that period of the year when the wells became sensitive and the flow from the strata was sluggish, that a fall in the barometer coincided with a rise in the water-line, and that under conditions of high barometric pressure the water-line was lowered. Percolating gauges also gave similar evidence, for after percolation had ceased and the filter was apparently dry, a rapid fall of the barometer occurring, a small quantity of water passed from the percolating gauges. The conclusion arrived at was, that atmospheric pressure exercises a marked influence upon the escape of water from springs.

On Evaporation and Excentricity as Co-factors in the Causes of Glacial Epoch, by the Rev. E. Hill, M.A.

On some Points in the Morphology of the Rhabdophora, by John Hopkinson.—The author, after reviewing the characteristics of the group, concludes from his investigation into the morphology of this group that they are the Palæozoic representatives of the recent Hydroida.

The Glacial Deposits of West Cumberland, by J. D. Kendall, C.E., F.G.S.—The extent, form, and inner nature of these deposits is first described; a number of new and important facts being brought forward on the distribution of boulders both in the boulder clays and in other glacial deposits. The conclusions arrived at from the facts are (1) that the boulder-clays were formed in the sea, partly by glacier action and partly by icebergs. The occurrence of boulders from distant localities, often in very different directions, in a matrix partaking of the character of the underlying rocks, is explained in an entirely new way. 2. That the middle sands and gravels are the result of marine and river action combined. 3. That the mounds of sands and gravels occurring in the mouths of valleys were accumulated by floating ice from pre-existing deposits. A somewhat novel explanation is given of the occurrence of boulders on higher levels than the rocks from which they were derived.

On "Flots," by J. R. Dakyns, M.A., Geological Survey of England and Wales.—The word "flot" is a miner's term for ore lying between the beds, or at certain definite horizons in the strata. In text-books flots are generally called "flats" or "flattings." They are of two kinds: (1) those connected with "cross-veins"; (2) those connected with courses of dun limestone. Firstly, cross-veins are veins (generally mere spar veins on Greenhow Hill) which cross and intersect or shift the metal veins, but which often bear ore at their intersection with the metal veins. Where these cross-veins cut the flot planes, ore is found. Secondly, similarly with courses of dun limestone. Dun limestone, so-called from its colour, is a dolomitised form of ordinary limestone. The dun lime occurs in beds or irregular masses, or more frequently in dyke-like courses, running north-north-west and south-south-east. These courses are often several yards or even fathoms wide, and where the dun course crosses the flot plane ore is developed along the joints between the dun and the white limestones. Ore is not found along the flot plane except at its intersection with the cross-veins or with the courses of dun limestone.

On the Lower Cambrian of Anglesea, by J. McK. Hughes, Woodwardian Professor, Cambridge.—In this paper the author gives the results of further examination of the basement beds of the Cambrian, which he has now traced all along the north-west flank of the Archæan axis of Llanfaelog. The sequence he found almost invariably was in ascending order:—(A) Quartz conglomerate passing up into (B) grit, which in turn becomes finer, and passed into (C) sandstones weathering brown, which get split up in their upper part by thin slabby shales; (D) black shales with subordinate beds of black (D 2) breccia, and occasionally sandstone in the lower part.

On the Gnarled Series of Amlock and Holyhead in Anglesea, by T. McK. Hughes, Woodwardian Professor, Cambridge.—The author offers the results of his inquiries into the age of certain schists which form the main mass of the rocks of northern and Western Anglesea, leaving for the present the consideration of the masses of somewhat similar rock which occur south of the Llanfaelog gneissic axis in the central and south-east part of the island. The author believes these felspathic gnarled rocks must be either the marine equivalents of the Bala volcanic series, or the result of a later (probably Silurian) denudation of those beds. As Lower May Hill (= Birkhill) fossils only occur in the slates immediately south of the area in question, the latter supposition is the only one tenable in the present state of the evidence.

Notes on the Subsidences above the Permian Limestone between Hartlepool and Ripon, by A. G. Cameron, Geological Survey of England and Wales.—In this paper attention is drawn to the numerous forms of shrinkages of the land-surface, often extending to considerable depths into the rocks beneath, observable over the top of the Permian rocks betwixt Hartlepool and Ripon. As a general explanation of their origin, it is suggested that where the underground water, flowing over the limestone surface, reaches the margin of the sandstone, it receives a check whereby it accumulates, forming a chain of dams or pools along the line of junction of these rocks. As denudation proceeds, hollows form above, until ultimately the phenomena of the pits appear. This being so, "the water bubbling and frothing all over" is explained without calling in the aid of river-action. Allusion is made to the Home Farm Colliery accident at Hamilton, N.B., in February, 1877, through a subsidence in the gravelly alluvium of the Clyde; also to the recent subsidences at Blackheath, near London, and to the extensive caverns in the hematite districts of Furness.

The Great Plain of Northern India not an old Sea-Basin, by W. T. Blanford, F.R.S.—The author described the distribution of land in the Indian Peninsula and the intervention of a vast plain traversed by the Indus, Ganges, and Brahmaputra. This plain has constantly been considered, both by geological and lithological writers, as the basin of a great sea; but on examining the evidence, there does not appear to be a single fact in favour of the sea having at any geological period occupied the Gangetic or eastern position of the plain. The tract is evidently an area of depression filled up to above sea-level, through a long period of geological range of time.

The Gold-Fields and the Quartz Outcrops of Southern India, by William King, Deputy-Superintendent (for Madras), Geological Survey of India.—The paper is a *résumé* of the knowledge ascertained through the author's original survey of the Wainád gold-field in 1874 and by the later surveys and examinations of others; also in his examination of the Travancore and other areas in the beginning of the year. The geographical distribution of the gold areas is briefly treated of as being at Manyapet, on the Godávari River, near Dúmbal, in the South Mahratta country, near Kolár in Mysore, at Salem, in part of the Travancore State, and in the Nilgiri and Malabar country; and these are reduced to the more important fields of Malabar (including Wainád, and the Nilgiris) and Mysore. The reefs of Wainád are developed to a remarkable extent over a very large area of country; but their gold-bearing quality is only displaced over a portion of this, chiefly in the south east of Wainád and in the adjacent low country of Malabar, in a generally east and west belt, the reefs outside of this being fewer and only very locally auriferous. The "leaders" or offshoots of the reefs in this belt are strongly and numerously developed, and they and the "casing" are rich in gold. The author expects the gold-yield to be seven pennyweights to the ton. He does not think that a paying return can be obtained on less than three pennyweights of gold to the ton.

Geology of the Island of Cyprus, by R. Russell, C.E.—The author described the physical features of the island as consisting of two great mountain chains, the axes of which are mainly parallel to each other, distinct from each other in structure and in physical matter. The southern range, rounded in outline, rises to 6340 feet; the northern range rises up from hummocky ground, on both sides, as it were, in one great continuous wall-like cliff. The central area consists of flat-topped irregular hills rising abruptly from the low ground, and therefore show more prominently than they would otherwise. The rocks which occur may be classified as follows:—

Post-Tertiary.	Blown sand.	
	Alluvium (vent).	
	Kavara (solidified surface).	
	Raised beach.	
	Sand and gravel (old river deposits).	
	Calcareous tuff and travertine.	
Tertiary.	Pliocene	Kerynia rock.
		Nicosia beds.
	Miocene	Idalian beds.
Secondary	Upper Cretaceous.	Konnos.
	Jurassic	Mount Hilarion limestone.
	Igneous rocks.	

The last upheaval of the island took place in a comparatively recent period, and was not more than fifteen or twenty feet in vertical height.

On some Sections in the Lower Palæozoic Rocks of the Craven District, by J. E. Marr, B.A., F.G.S.—The author showed by means of a thin band containing *Phacops elegans*, Boeck and Sars, that a series of beds consisting of pale green shales, underlain by black shales, passing below into a conglomerate which rested unconformably upon the Bala beds (the whole exposed in Austisich Beck, near Settle), were the equivalents of the Stockdale shales of the Lake District, and of the May Hill beds of the Continent. The beds are lithologically similar to those of the Lake District, and, like them, are surmounted by blue flags containing *Monograptus priodon* and *M. vomerinus*.

Life in Irish and other Laurentian Rocks, by C. Moore, F.G.S.—The author drew attention to certain forms found by a microscopic examination of specimens of certain Laurentian and other Palæozoic limestone prepared by trituration, solution in acid, and washing. These forms were clearly those of organic structures, some apparently hairs and other feather barbs. The author considered that he had taken precautions to eliminate

sources of error, through admixture of foreign materials, and he was led to think that the organisms belonged to the rocks.

The Subject-matter of Geology and its Classification.—Prof. W. J. Sollas, M.A., stated his object was to remove certain prevailing misconceptions as to the aim and scope of geology. The accepted definition of geology as "the history of the earth's crust and the fossils it contains," was considered to be both too wide and too narrow; the former since it includes palæontology, which, so far as it is a study of forms of life, belongs to biology; and too narrow, since the science of the whole, necessarily embraces much more than a study of its crust. Geology is one of the group of concrete sciences which include astronomy, geology, and biology. The scope of geology, or the science of the earth, is so wide, that a fresh classification of its subject-matter is required, and the author proposes *Morphological Geology*:—embracing geography, petrology, lithology, and mineralogy corresponding to anatomy and histology in biology; minerals, rocks, rock masses, constituting the earth's crust as cells, tissues, organs constituting living organisms, while palæontology is a study of successive morphological states, corresponding to embryology or development. *Physiological Geology*, considering the movement of the earth as a whole, and of all activities produced upon it, by extrinsic and intrinsic forces, acting singly or in combination; it rightly includes meteorology, hydro-geology, as well as the physiology of the earth's crust. *Distributional Geology* seeks to determine the distribution of the earth in time and space, and *Otiological Geology* corresponds roughly to what is known as cosmogony.

Exploration of a Fissure in the Mountain Limestone at Raygill, by James W. Davis, F.G.S.—Attention was first called to this fissure by Mr. Tiddeman about eight years ago. It occurs in a quarry in Lothersdale, about five miles from Skipton. The mouth of the cavern is blocked with glacial drift; under this occurs a finely laminated clay, beneath which is a brown sandy clay with well-worn boulders. The fissure, when excavated, proved to be forty feet in length, horizontal, with a second branch, both of which are abraded and smoothened by the action of running water. Contains bones of *Elephas*, teeth of *Hippopotamus*, *Rhinoceros leptorhinus*, remains of the roe-buck and hyæna, and one or two teeth of lion, and a single tooth of bear.

On the Zoological Position of the Genus Petalo-rhynchus, Ag., *a Fossil Fish from the Mountain Limestone*, by J. W. Davis.—The species described resemble genera *Janassa*, Munst., and with it appear to occupy an intermediate position between the genera *Myliobatis* and *Cestraciontes*.

On Diodontopsodus, Davis, *a New Genus of Fossil Fishes from the Mountain Limestone at Richmond in Yorkshire*, by James W. Davis, F.G.S.—These teeth resemble those of the modern fish Diodon.

Preliminary Remarks on the Microscopic Structure of Coal from East Scotland and South Wales, by Prof. Williamson, F.R.S., Owens College.—This subject will not be worked out until ten years, but he described layers of vascular tissue which can be separated layer by layer, while in other cases the charcoal layer on the surface of the coal and the organic structure is not capable of separation, and he stated that charcoal contains a tubular structure, like tissues of ordinary bark. The association of tissues resembles that of Cycadian plants; and referred to the genus *Cordaites* having been proved to belong to this group by M. Renault; the author has made nearly a thousand distinct observations on the structure of coal. Separates ordinary coal with large quantities of mineral charcoal, with macrospores of Lepidendroid plants filled up with myriads of microspores which were certainly not floated to the spots, from the *paraffine coals* which do not contain these large macrospores. He divides coals into "Iso-sporous" coals and "Heterosporous" coals; both alound in *Cordaites*, which form the mineral charcoal.

On an International Scale of Colours for Geological Maps, by W. Topley, Geological Survey of England.—The author described the objects of the International Geological Congress which is to meet at Bologna this month. Three main subjects are there to be discussed, (*a*) colours and signs for geological maps, (*b*) nomenclature of rocks and formations, (*c*) nomenclature of species. This paper is concerned only with the first of these questions, and especially with the resolutions passed by the English Map Committee, of which Prof. Ramsay is president, and the author secretary. At present all countries and many map-makers in each country have different systems of colouring maps, and it is necessary carefully to study the index, or scale of colours used, before the map can be at all understood. The Congress proposes to frame some scheme of colouring which can be used and readily understood by all nations. It may not be possible, at least for some time to come, to obtain any alteration in national surveys in progress. But it is to be hoped that in new small-scale maps the scheme to be decided on will be adopted. One important point which the Congress proposes is the preparation and publication of a general map or atlas of Europe, compiled under the authority of the Congress, from the various national surveys and the work, of independent observers. The scheme of colouring proposed is one based on the order of colours in the solar spectrum, violet denoting the older rocks. Bright reds are reserved for igneous rocks; metamorphic rocks will be shown by dark bands of colour over the colour denoting the age; to these will be added bands of colour showing the period at which metamorphism has taken place, when such fact is clearly established: thus, Silurian rocks metamorphosed in Cretaceous time would be shown by violet striped with alternate lines of dark violet and green. The sub-divisions of a formation will be shown by shades of the body colour, the darkest shade denoting the oldest sub-division. The letter denoting the formation will be the capital initial letter of the name of the formation; with very small arrangements one system of lettering can be made to apply to all countries. It has been found impossible to adhere strictly to the order of colours of the spectrum, and an interpolation has been made of browns and greys for the series of beds between the Silurian and the Lias. Examples of maps and tables of strata coloured according to the plan adopted were exhibited, as were also a series of Indexes of Colours issued at various dates by the Geological Survey, commencing with one in MS. by Sir H. de la Bêche in the year 1832. The author also drew attention to a proposal made by Mr. J. W. Salter before this Association in 1847, and again at the International Exhibition in 1862, to colour geological maps in the order of colours of the solar spectrum. The plan recommended by the English committee differs considerably in detail from that of Mr. Salter.

On the Rhætics of Notts, by E. Wilson, F.G.S.—The author gave a summarised account of the Rhætic series in Nottinghamshire. The Rhætic sections of this district already known to geologists comprise those at Gainsboro', Newark, and Elton. The author described several additional new sections in the Rhætics of the county—viz. at Cotham and Kilvington between Newark and Bottesford; at Barnstone, between Bingham and Stahern; the boring for coal at Owthorpe, near Colston Bassett; and the section at Stanton-on-the-Wolds, between Nottingham and Melton Mowbray. A list of the Rhætic fossils of Notts was given, and the presence of bone-beds noticed. The author could not agree with certain geologists that the green marls which are found beneath the Paper shales in Notts (nor probably also the "Tea-green marls" of the West of England) belong to the Rhætic series, but took them to be Upper Keuper marls, once red in colour, which had become discoloured by some deoxidising agent, probably carbonic acid evolved during the decomposition of the organic matters of the fossils of the Paper shales. For, in lithological character the green marls agreed with underlying beds in the Keuper, but differed markedly from the overlying Rhætics; then there was every appearance of a passage between the green marls and the underlying red and green marls of the Keuper; and, lastly, the green marls, like the rest of the Keuper marls, were practically unfossiliferous, while with the commencement of the Paper shales we get the remains of an abundant and distinctly marine fauna, in part Liassic.

Notes on the Cheshire Salt-Field, by C. E. De Rance, F.G.S., of H.M.'s Geological Survey.—The author described the brine-springs of the Keuper marls in Cheshire and part of Shropshire as having been derived from rainfall absorbed at the line of the original outcrop of the beds of thick rock-salt, which is represented by a porous bed. These waters flow out by pressure in various natural springs, and are bored into by the wells or artesian shafts of the brine-pumpers. The natural solution of the rock-salt has caused the characteristic subsidences that occur in the district. Northwich subsidences, however, have been chiefly caused by bad mining.

On the Strata between the Chillesford Beds and the Lower Boulder Clay. "*The Mundesley and Westleton Beds*," by J. Prestwich, M.A., F.R.S., Professor of Geology in the University of Oxford.—The beds between the Chillesford Clay and the Lower

Boulder Clay present such a series. Its exhibition on the coast of Norfolk, although very limited, is accompanied by special palæontological features that have caused it to be divided into the number of local beds which have been described by Trimmer, Green, Gunn, Wood, and Harmer, the author, Reid, Blake, and others. It includes the "Laminated Clays" of Gunn, the "Bure Valley Crag" of Searles-Wood, the "Westleton Shingle" of the author, and the "Rootlet-bed" and "Norwich Series" of Blake. Without reverting at present to the exact correlation of the several beds in the Norfolk area, respecting which there is still some difference of opinion, the author suggests that they should be included under a general term founded on the localities where, on the one hand, their varied palæontological characters are exhibited, and on the other where their peculiar petrological characters are well marked—characters which the author proposes to show, in another paper, have a very wide range, and serve to mark an important geological horizon in some interesting questions of local physical geology. The Mundesley beds were described by the author in 1860, and consist of alternating beds of clay, sands, and shingle, some containing freshwater and others marine mollusca, with a forest-growth and mammalian remains at their base; and again in 1871, including them in his Westleton group (No. 5 in the author's sections), which he showed to consist entirely of great masses of well-rounded shingle, with intercalated seams containing traces only of marine shells. Seeing the inconvenience of attaching the same term to the two very distinct series of beds, and that it may conflict with other local terms, the author now proposes to group this series under the term of "The Mundesley and Westleton Beds," indicative of their stratigraphical position in Norfolk, and of characters in Suffolk which serve to trace them in their range westward and inland to considerable distances beyond the Crag area, to which alone these beds have hitherto been restricted. At the same time it may be convenient, for brevity, to use one term only in speaking of typical cases.

On the Upper Bagshot Sands of Hordwell Cliff, Hampshire, by E. B. Tawney, M.A., F.G.S.—The descriptions of former writers having been cited, it was found that there were two main views regarding the affinities of these sands, which occur in the cliff between Long Mead End and Beacon Bunny. The view formulated by the distinguished foreign geologists, D'Archiac, Dumont, Prof. Hebert, and Prof. C. Mayer, is that they are parallel to the upper sands of the Beauchamp (= Barton) period, and allied, therefore, to the marine Barton beds. This view is much the same as that of E. Forbes, and the Geological Survey, who called them the Upper Bagshot Sands. Latterly Prof. Judd has sought to revive the term Headon-Hill Sands for them, presuming them to be most nearly connected with the Headon series, and extending the bounds of that series to receive them. The author now gives a list of twenty-eight species obtained from the bed at Long Mead End; of these 35 per cent. are common to the sand and the Barton beds, but do not occur in the Headon series; while only 21·4 per cent. are common to the sand and Headon series, but do not occur in Barton beds. It is shown that this sand belongs to the zone of *Cerithium pleurotomoides*, Lam., and is exactly parallel to the sands of Mortefontaine, which belong to the same horizon, constituting the upper portion of the Beauchamp deposits. This is altogether below the *C. concavum* zone. From these sands being intimately connected with the Barton beds in both areas, it is held that the term Upper Bagshot is the most fitting designation that has been proposed for them.

NOTES

THE Emperor of Germany has, by Imperial Decree dated June 1, 1881, awarded the Gold Medal of Merit for Agriculture to Mr. Lawes and Dr. Gilbert jointly, in recognition of their services for the development of scientific and practical agriculture.

THE death is announced, at the age of sixty-two years, of Mr. Frederick Currey, F.R.S., F.L.S. Mr. Currey was well known as a botanist, and was secretary to the Linnean Society from 1860 to 1880. It is stated that Mr. Currey has left his valuable collections of fungi to Kew.

THE honour of knighthood has been conferred upon Dr. G. C. M. Birdwood, C.S.I., of the India Office; and also upon Dr. John Kirk, H.M. Political Agent and Consul-General at Zanzibar, well known as the friend of Livingstone, and naturalist to his second exploring expedition, and as having done so much to promote African exploration.

THE Sedgwick Memorial Fund (Cambridge) now amounts from subscriptions and interest to more than 14,000*l.*, but this sum is not sufficient to build the new geological museum which it has been decided to erect in honour of the late professor. As, however, the present museum was built partly by subscriptions collected mainly through the exertions of Prof. Sedgwick, with a view to the erection of a geological museum, as well as of the library and other University buildings, the value of the portion occupied by the present museum should be taken into account in estimating the sum available for the new memorial building. An architect has been consulted as to the possibility of erecting a new geological museum and a chemical laboratory on the vacant space in front of the new museums and lecture-rooms facing Pembroke Street, but after examination of his plans and report it was found that the proposal could not be carried out, and it has consequently been decided to await the result of further negotiations for the purchase of the contiguous property. The recent acquisition by the University of some adjoining land will, it is hoped, diminish the difficulties now existing in the way of finding a suitable site for the erection of the new geological museum.

A LONG and interesting article in the *Daily News* of Tuesday describes the progress which has been made in carrying out the scheme of Mr. Holloway for the erection of a college for the education of young ladies. Mr. Holloway's endowment is of the amplest liberality; the building is all that could be desired, and is in a fair way of being completed; there is no danger of the institution becoming one for the benefit of the teachers and not of the students; the programme of education is meant to place science on a footing of absolute equality with learning. "The governing body will consist of twenty-one persons, to be appointed partly by the University of London, and partly by the Corporation of London, and it is stipulated that a certain portion shall always be women. Religious opinions are not in any way to affect the qualification for a governor. It is the founder's desire that power by Act of Parliament, Royal charter, or otherwise, should be eventually sought to enable the college to confer degrees after due examination; and that until such power is obtained the students shall qualify themselves to pass the Women's Examination of the London University, or any examination of a similar or higher character which may be open to women at any of the existing universities of the United Kingdom. The curriculum will not be restricted to subjects enjoined by any existing university. Instead of being regulated by the traditions and methods of former ages, the system of education will be mainly founded on studies and sciences which the experience of modern times has shown to be most valuable, and as best adapted for the intellectual and social requirements of students. The governors will therefore be empowered to provide instruction in any subject or branch of knowledge which shall appear to them, from time to time, most suitable for the education of women; and the curriculum of the college will not discourage students who may desire a liberal education apart from the Latin and Greek languages." All this is admirable, and we trust the spirit of the founder's wishes will be faithfully carried out. This building and the Sanatorium are not far from Virginia Water, and the total cost, with endowments, will probably amount to close upon a million.

IN connection with the Smoke Abatement Committee, an International Exhibition and trials of smoke-preventing appliances will be held in the East and West Arcades, and in buildings adjoining the Royal Albert Hall, at South Kensingto

from October 24 to November 26. Gold, silver, and bronze medals and certificates of merit will be awarded upon the report of a special committee. Regulations and forms of application for space may be had on application (by letter) addressed to Mr. Gilbert R. Redgrave, Superintendent of the Exhibition, Exhibition Buildings, Queen's Gate, South Kensington; or to Mr. W. R. E. Coles, Hon. Secretary to the Smoke Abatement Committee, 44, Berners Street, W.

THE Parkes Museum is closed until the end of September. In October it will again be opened free to the public on Tuesdays, Thursdays, and Saturdays, and during the winter lectures on sanitary science will be given in the Museum. The lectures will be illustrated with the sanitary appliances deposited in the Museum, which now include many new contributions sent from the recent Medical and Sanitary Exhibition at South Kensington. We believe it is intended to distribute the awards to the exhibitors at the Exhibition, at the second public annual meeting of the subscribers to the museum in October or November.

A NEW College of Practical Engineering has been opened at Muswell Hill, near London, under the auspices of a number of eminent practical engineers, among whom we may mention Sir John Anderson, late chief engineer at Woolwich, Sir Henry Bessemer, Sir R. M. Stephenson, Sir Joseph Whitworth, Bart., and Mr. Charles Manby, honorary secretary of the Institution of Civil Engineers. The principal of the College is Mr. John Bourne, C.E., author of several works on the Steam Engine and other kindred subjects. The instruction it is stated will combine the best theory with the best practice.

AS a special number of the *Journal* of the Society of Telegraph Engineers, a valuable Guide-Book to the British Section at the Paris Electrical Exhibition has been issued, edited by Prof. W. E. Ayrton, F.R.S.

THE success of the Siemens electrical railway in Paris is very great, and the mode of locomotion very highly prized by Parisians. It is certain that steps will be taken after the Exhibition for rendering it a permanent feature of the French capital.

DURING the recent meeting of the British Association a conference of delegates from scientific societies was held, and the chair was occupied by Mr. W. Whitaker, F.G.S., Norwich Geological Society. The following resolution was adopted:—"That a committee be appointed, consisting of Sir Walter Elliot, F.R.S., Mr. H. George Fordham, Mr. John Hopkinson, Mr. G. J. Symons, F.R.S., and Mr. W. Whitaker, to arrange for a conference of delegates from scientific societies to be held at the annual meetings of the British Association, with a view to promote the interests of the societies represented by inducing them to undertake definite systematic work on a uniform plan; that Mr. Fordham be the secretary, and that the sum of 5*l.* be placed at their disposal for the purpose." An interesting conversation followed as to the best methods of stimulating the local societies to more active work. Mr. John Hopkinson, F.L.S., F.G.S., gave a most interesting account of the operations of the Hertfordshire Natural History Society. He had induced several members to take up the registration of the rainfall, and they had now twenty-eight observers of rainfall in their small county. Every one did not care about such observations, but there were plenty of other matters needing attention. Other members had been induced to take up the recording of the migration of birds, the flowering of plants, the appearance of insects, and other periodical phenomena; and the club furnished about one-third of the entire phenological observers of the Meteorological Society. They were also preparing lists of the fauna and the flora of the county, and one ornithologist was collecting a record of all the birds that are, or have been, observed in Hertfordshire. A resolution was unanimously adopted appointing Sir Walter Elliot and Messrs. Fordham, Hopkinson, Symons, and Whitaker a committee to arrange for the next Conference, and to send out a circular to the local scientific societies pointing out the work of the various committees of the British Association to which they might render aid, and other scientific work of a systematic character that they might usefully undertake.

AT a recent meeting of the Banburyshire Natural History Society Mr. E. A. Walford read a note "On the Occurrence of a Fire-ball at Watergall" on August 23. In answer to Mr. Walford's queries, Mr. Fessey, jun., had sent an account as follows, dated "Watergall, Leamington, August 30:—As regards the fire-ball, I was about 200 yards from it, in a waggon hovel. I saw it directly it left the sky, as I was looking in that direction at the time. When I first saw it, it looked like a ball of fire, about as large as a dinner-plate. It slowly descended, and I have no doubt I could have run twenty yards from the time I first saw it until it struck the ground; but when about fifteen to eighteen feet from the ground, it exploded with a loud crash, quite as loud as a cannon, distinctly before the thunder, which was very loud also. The explosion shook the whole buildings. I certainly thought the slates were falling in, but when it exploded one part struck the hedge, making a hole in the ground about a foot deep, and laying all the roots bare, but not damaging them. For some time the place looked all on fire, and there was a considerable quantity of smoke when it hit the ground, lasting for a second or two. It was seen by myself and four men. They also agree with me that this is as near as possible a correct explanation of it. We dug the hole out yesterday, but found nothing. The soil was blackened for several inches deep."

DR. C. S. MINOT, in a paper read at the Cincinnati meeting of the American Association, recommended the following method of mounting chick embryos whole. The blastoderm is removed and cleaned in the usual manner, and then floated out on a glass slide, where it remains permanently. It is carefully spread out and allowed to dry until the edges become glued to the slide. It is then treated with a 0·5 per cent. osmic acid solution, until a slight browning occurs. Stain with picrocarmine. The next step is particularly important, because it prevents the further darkening by the osmium, which otherwise injures or ruins the specimen. Pour Müller's fluid, or 0·5 per cent. chromic acid solution, on the slide, and leave it over night. The next morning the blastoderm is ready for dehydration by alcohol, and mounting in the usual manner in balsam or Dammar lac. Embryos prepared in this manner make particularly beautiful specimens.

THE winter session of the Charterhouse Science (the largest in the United Kingdom) and Art School and Literary Institute will, under the presidency of the Rev. Henry Swann, M.A., commence on September 24. During the late session about 700 students attended this institution; and of this number nearly 500 presented themselves for examination, and were successful in obtaining no less than 100 Queen's prizes. At a nominal fee instruction of a practical character is given in most of the sciences. Chemical students have the opportunity of working in a well-fitted laboratory capable of holding sixty students. During the session Mr. W. B. Carpenter, F.R.S., will deliver a course of lectures on physiology, to which teachers will be admitted free. This will prove a great boon to the teachers of the metropolis. Dr. Gladstone, F.R.S., Prof. Farrar, Mr. Sydney B. J. Skertchley, F.G.S., and others will lecture during the session.

THE Berlin Museum is now the fortunate possessor of archæological treasures which are perfectly unique. They are the long-expected sculptures from the Central American field of ruins at

Santa Lucia de Cosumalgapan, Guatemala, purchased for the Museum by Prof. Bastian when upon his American journey.

A SEVERE earthquake was felt three weeks ago in the southern part of the North Island, New Zealand. No lives were lost, but in some of the townships in the Manawater district scarcely a chimney was left standing. In Foxton, for instance, no less than 250 were thrown down. Fissures extending for many miles are reported to have been made, and the railway line was rendered unsafe in that neighbourhood, owing to the undulations of the earth alternately raising and depressing the rails. Since the large shock a good many of a slight nature have occurred. Two shocks of earthquake, each lasting from four to five seconds, were felt at noon on September 2 at Spalato in Dalmatia. The earthquake, which was accompanied by a subterranean rumbling, passed from the south-west to the north-east. It also made itself felt in the neighbouring islands of Brazza and Mascarsa, and in the town of Sebenico. A shock of earthquake was distinctly felt by several individuals at Courtown House, Gorey, Ireland, on August 27, at a quarter to five o'clock. Many heard a rumbling noise as of thunder, some noticed the rattling of doors and windows, and one experienced what he called a "shiver." Lord Courtown noticed a rumbling noise, coming apparently from the north, passing under the house, and so away to the south; the door of the room in which he was sitting rattled. A slight shock of earthquake was felt at Naples at eight o'clock on Saturday morning. At about the same hour severer shocks took place at Popoli, Pescara, and Orsogna, in the Abruzzi. The seismographic instruments on Mount Vesuvius show great activity. In the Abruzzi the earthquake shock has damaged several houses at Chieti and Castelfrentano, where some people have been wounded. At Lanciano two people were killed. At Orsogna one was killed and several were wounded. At Atessa the church of St. Giustina was seriously damaged. There is a great panic everywhere amongst the population. A shock of earthquake occurred at Sanpietro Brazza (Dalmatia) on August 29, at 9 p.m. It lasted four seconds. On September 2, at 10.48 a.m., two strong oscillations were felt at Sign, Spalato, and Brazza (in Dalmatia). Direction east-west. Over forty shocks of earthquake have been felt at Khoi, Persia, between the 28th ult. and September 11. Some houses were destroyed, but no lives have been lost. Most of the inhabitants have left the town, and are encamped outside. The direction of the earthquakes was from north to south. The shocks were accompanied by rumbling noises.

A TERRIBLE disaster has occurred at Elm, a village in the Canton of Glarus. The place has been almost destroyed by a fall of rock. It is believed that at least 200 persons are buried beneath the ruins.

THE German Ornithological Society held its annual meeting early this month at Hamburg. Prof. Landois (Münster) spoke on birds' nests and on the origin of egg-shells; Dr. Reichenow (Berlin) on the classification of ducks.

ACCORDING to the last report of the director of the Central Sanitary Bureau of Japan, the Central Government has granted the necessary funds for the establishment of a hospital in the capital for the special treatment of *kakke*, a disease which has been spreading more and more in the country, and one of the usual symptoms of which is œdema of the legs. It is intended to investigate carefully the causes and proper treatment of the disease at this institution. The average mortality, from all causes, is given at 10·43 in every 1000 of the population, and is stated to be lower than that of places in Europe and America under similar conditions. The director observes, however, that the registration of deaths is not efficiently carried out; but measures are being taken to render this as complete and accurate as possible. It is noticeable that deaths from diseases of the digestive organs and nervous disorders greatly preponderate over all others. In the former the proportion is 24·1 per cent., and in the latter 23·1. Small-pox was the most destructive epidemic of the year, but the number of annual vaccinations is largely increasing. During the year covered by the report it was 1,659,298.

THE second part of Dr. Lang's "Butterflies of Europe" is before us, and quite justifies our mostly commendatory remarks in a recent number. When the work more nearly approaches completion we may probably again find occasion to notice it.

FROM Surgeon-Major Bidie's Report on the Government Central Museum at Madras, we see the number of visitors during 1880–81 was less than in the previous years, due, however, to trivial and temporary causes. The total number of visitors was 173,898, of whom 39·36 were women and girls. Many of course go simply for curiosity, but a very considerable number visit the museum for the express purpose of obtaining information, and there seems no doubt that, under Mr. Bidie's energetic and intelligent management, the institution is doing much good. Very considerable additions have been made during the year, and the whole is in a fair way of being catalogued.

THE additions to the Zoological Society's Gardens during the past week include two Greater Black-backed Gulls (*Larus marinus*), British, presented by Mr. A. Allen; a Blue-shouldered Tanager (*Tanagra cyanoptera*) from South America, presented by Mr. Ernest L. Marshall; a —— Tanager (*Tanagra*, sp. inc.) from Brazil, presented by Dr. Arthur Stradling; a Green Lizard (*Lacerta viridis*), South European, presented by the Misses Parry; two Pantherine Toads (*Bufo pantherinus*) from North Africa, presented by Mr. R. E. Holding; six Common Lizards (*Lacerta vivipara*), two Smooth Snakes (*Coronella lævis*), two Sand Lizards (*Lacerta agilis*), British, presented by Mr. J. T. Mann; a Grey Parrot (*Psittacus erithacus*) from West Africa, four Passerine Parrakeets (*Psittacula passerina*), two Lineated Finches (*Spermophila lineata*) from South America, a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, deposited; six Common Chamæleons (*Chamæleo vulgaris*) from North Africa, purchased. The additions to the Insectarium include larvæ of the Tussch Silk Moth (*Attacus mylitta*); several larvæ of the Poplar Hawk Moth (*Smerinthus populi*), presented; an imago of the Death's-Head Moth (*Acherontia atropos*), presented by Mr. M. H. Temple, Warwick, and two specimens of *Ceratocampa ixion*, bred from pupæ received a short time since from South America, also many species of aquatic Coleoptera from Askham Bog, near York, presented by Mr. W. A. Forbes, including *Haliplus elevatus*, *Hyphydrus ovatus*, *Hydroporus rufifrons* and *lineatus*, *Colymbetes exoletus* and *grapei*, *Ilybius ater* and *uliginosus*, *Agabus dispar* and *abbreviatus*, *Noterus sparsus*, *Helophorus aquaticus*, *Hydrobius fuscipes*, *Philhydrus melanocephalus*.

OUR ASTRONOMICAL COLUMN

THE DEARBORN OBSERVATORY, CHICAGO.—The annual report from Prof. Hough to the Board of Directors of the Chicago Astronomical Society, dated May last, has been issued. The planet Jupiter has been made a special object of study with the great equatorial, the first observation having been secured on May 6, 1880, and the last on January 30, 1881. The observations made at the Dearborn Observatory do not support the idea that the surface of the planet is "subject to sudden and rapid changes, which may be accomplished in a few days or even a few hours." On the contrary, the observations in question show that all minor changes in the markings or spots have been slow and gradual. "In fact the principal features have been permanent, no material change being detected by micrometer measurement." With regard to the rotation of Jupiter, the discussion of the measures on the great red spot made from September 25, 1879, to January 27, 1881, or over a period of 490 days, gave

for the mean value 9h. 55m. 35·2s., but when the individual observations are compared with it, a well-marked maximum displacement of the centre of the spot, to the amount of 1″·4, is exhibited, apparently indicating that it gradually oscillated to this extent in longitude, which on the surface of Jupiter corresponds to about 3200 miles. The observations however may be well represented by making the period of rotation a function of the time; thus the period 9h. 55m. 33·2s. + 0·18s. $\sqrt{t}$ is found to satisfy all the measures with a mean maximum error of 0″·5: the zero-epoch being September 25, 1879, and t the number of days after that date. The mean-rotation period derived from observations of polar spots is 9h. 55m. 35·1s., that deduced from the small spots indicating an average displacement during two months of 2″, or about 4600 miles. The rotation resulting from the observations of equatorial spots is 9h. 50m. 9·8s. with uniform motion. Prof. Hough states that the actual size of the great red spot, as seen with the Chicago telescope (18½ inches aperture) is—length, 29,600 miles; breadth, 8300 miles; and he remarks that smaller telescopes make the approximate length considerably less than the real value.

The nebula near Merope in the Pleiades, of which so much has been written, was not seen with the Chicago refractor in 1879, but as so many observers have described it, Prof. Hough, in conjunction with Mr. S. W. Burnham, made a thorough examination of the locality, with the result that they satisfied themselves that "the nebula did not exist, but that the appearance described by different astronomers was wholly an optical illusion, due to the glow from *Merope* and neighbouring stars." This opinion will probably be disputed in many quarters.

THE WASHBURN OBSERVATORY, WISCONSIN.—No. 1 of "Contributions from the Washburn Observatory, of the University of Wisconsin," has been received. The establishment is under the direction of Prof. Edward S. Holden, late of the Naval Observatory, Washington. Work was commenced in the latter part of April in the present year, with the Clark refractor of 15·56 inches aperture, and Prof. Holden has had the good fortune to secure the co-operation of that eminent observer, Mr. S. W. Burnham, who left Chicago at the beginning of April to accept a post in Washburn Observatory, and although the publication to which we refer is dated May 31, some five weeks after the commencement of operations, thirty-four new double-stars had been detected and measured by Mr. Burnham, and a number of other doubles, discovered in the course of zone-observations in which Prof. Holden took part, were also measured. In addition we have a list of new nebulæ detected in the zone-observations, several of which appear to deserve special attention. On May 2, in R.A. 18h. 8m. N.P.D., 108° 20′, a void space was remarked in the Milky Way; it is thus described: "This is a black circular hole (10′) in the Milky Way. The stars around it are excessively crowded, and inside there are but two stars, one 10 mag., the other very small."

The number of newly-discovered objects—double stars and nebulæ—of which we have the particulars in this first "Contribution" from the Washburn Observatory, is quite extraordinary, considering the few weeks over which observations have extended. We wish continued success to the Observatory of the University of Wisconsin.

SCHAEBERLE'S COMET.—The following meridian observations S.P. of Comet *c* 1881, made with the transit-circle at the Radcliffe Observatory, Oxford, have been communicated by Mr. F. J. Stone, the Radcliffe observer. The N.P.D. is uncorrected for parallax.

	G.M.T.	R.A.	N.P.D.
	h. m. s.	h. m. s.	° ′ ″
July 31,	9 54 47·5 ...	6 28 21·6 ...	44 3 46·1
(*a*) Aug. 2,	9 56 28·0 ...	6 37 55·6 ...	42 57 (36)
4,	9 59 56·5 ...	6 49 17·7 ...	41 47 13·3
6,	10 6 1·3 ...	7 3 10·6 ...	40 35 47·9
10,	10 29 50·1 ...	7 42 55·6 ...	38 21 31·6
(*b*) 19,	12 35 2·4 ...	10 23 57·4 ...	40 44 50·7

(*a*) Comet very faint. Only an approximate observation.
(*b*) Much brighter. Observation good.

ENCKE'S COMET.—The early observations of this body point to a negative correction of the mean anomaly to the extent of 3′, which corresponds to a retardation in the time of perihelion passage of about 0d·169. The perturbations from the action of Jupiter during the last revolution have been much greater than between 1875 and 1878, in which latter year the necessary correction to the mean anomaly given by the calculations of the late Dr. von Asten, was about one-third as great, but in the same direction. The work of his successor, Dr. O. Backlund of Pulkowa, has been executed with a most thorough determination of the planetary perturbations, which is extended to the preparation of the ephemeris.

The first glimpse of the comet, so far as we know at present, was obtained by Dr. Hartwig and Prof. Winnecke with the six-inch comet-seeker at the Observatory of Strassburg on August 20. Five days later it was clearly seen in the same instrument as a nebulosity 4′ in diameter.

ELONGATIONS OF MIMAS.—The following Greenwich times of apparent preceding elongations of this difficult object depend upon the same elements as previously used in this column:—

h. m.	h. m.	h. m.
Sept. 19 at 15 36	Sept. 21 at 12 50	Sept. 23 at 10 4
20 at 14 13	22 at 11 27	24 at 8 41

GEOGRAPHICAL NOTES

THE International Polar Conference, which was held last year at Berne, and the previous year at Hamburg, met last month at St. Petersburg. The object of this Conference is the organisation of a series of stations around the Polar area for the continuous prosecution of scientific observations. Since its last meeting it has lost Lieut. Weyprecht, who was the originator of the idea of such a scheme. Delegates were present from all the leading European States except England, and from the United States of America. The first subject discussed was the time at which observations should be taken, and their frequency. Observations will begin for all the expeditions in the Polar regions, as also for observations in the temperate zones, as soon as possible after August 1, 1882, and will finish as close as possible to September 1, 1883. All the meteorological and magnetical phenomena will be observed hourly during all this time; and, besides, there will be taken on the 1st and 15th of each month magnetic observations every five minutes for twenty-four hours, and every twenty seconds during an hour of the day fixed on in advance, and that everywhere after the mean time of Göttingen. These latter observations have for their special end to obtain a perfect knowledge of perturbations or magnetic storms, and their connection with the aurora borealis. On the basis of a programme of observations to be made, already elaborated by the Hamburg Conference, the obligatory meteorological observations were discussed—*i.e.*, observations which all the stations must make in order to insure the scientific success of the enterprise. The result of the discussion was the fixing of the principles, and in part also of the methods and instruments of observation, to insure the accuracy and comparability of the meteorological observations to be made. Happily the Conference numbers among its members several distinguished men of science, who have acquired in former expeditions in the Polar regions very great experience of the difficulties to be met with in taking observations, who were able to give advice useful in obviating beforehand those obstacles, by the arrangement of the instruments, and by the method of taking observations. One day was devoted by the Conference to visiting the celebrated meteorological and magnetic observatory of Pavlovsk, and discussing there the choice of the best apparatus. The members visited in detail the provisional installations which have been made at the observatory for inspecting the magnetic instruments intended for the Russian expedition to the mouth of the Lena. At the third sitting of the Conference, the magnetic observations were discussed: these also meet with difficulties unknown in temperate zones. It is not only the great cold, but also the feebleness of the horizontal intensity of terrestrial magnetism, as also the frequency and greatness of the perturbations, which render observations very difficult and delicate. At the fourth meeting the Conference was occupied with observations on the aurora borealis, and with the question of facultative observations, those which are recommended to the expeditions, without being considered indispensable—as observations on the temperature of the soil, evaporation, terrestrial galvanic currents, atmospheric electricity, &c. The conference, among other things, decided to apply to different institutes to assure their co-operation, and to request magnetic observatories in the temperate zones, especially those in the southern hemisphere, to participate in the simultaneous observations, as also to ask the directors of the telegraphs of different countries to study more accurately terrestrial

galvanic currents in the telegraphic wires when aurora borealis or magnetic perturbations appear. Finally the assembly unanimously approved three proposals by Count Wilczek:—1. To found, if possible, a special publication to convey more quickly to the knowledge of the scientific world, as well as to the leaders of the expeditions, the proposals and reports concerning the expeditions, as also their first results. 2. To leave, if possible, on the spot the buildings and other arrangements likely to be useful to future expeditions of the same kind, and to recommend them in each country to the care of navigators or of the inhabitants. 3. To ask railway and steamboat companies to grant a reduction in the fares for the staff and effects of the various international Polar expeditions. The stations proposed, we may state, are two on the north coast of Siberia, one in Novaya Zemlya, one in Spitzbergen, one on Jan Mayen Island, one on the west coast of Greenland, one at Lady Franklin Bay, one in the Behring's Strait region, and the participating countries are Russia, Sweden, Denmark, Germany, Austria, and the United States.

On the 3rd of next month the members of the Italian scientific expedition for the exploration of the Arctic Seas will embark at Genoa in one of Lovarello's steamers. The zoology will be under the care of Dr. Vinciguerra; the botany will be confided to Dr. Lorenzo, at present residing at Buenos Ayres; mineralogy and geology to Prof. Lovisato, of the University of Sassari; and to Lieut. Roneagli the artistic department is given, for which purpose he will take photographic apparatus, &c. At Buenos Ayres the Commission will embark on a vessel belonging to the Argentine Republic. Lieut. Bove, who will take the command of the expedition, has already left for Buenos Ayres.

The U.S. Government have been officially advised of the arrival of Lieut. Greeley's Polar Expedition at Lady Franklin Bay, six days after leaving Upernivik. The expedition entered Discovery Harbour on August 11, where a station was formed. The party were all well and plentifully provided.

Advices from Copenhagen state that the news received from the Dutch Polar Expedition on board the schooner *Willem Barents* is very unfavourable. Owing to the continuous ice barrier, which extends nearly to Norway, Spitzbergen could not be reached, nor yet even the Bear Islands; and after one more attempt to force through northward, the expedition will return home, as the captain is convinced that this year Novaya Zemlya is completely inclosed in a barrier of ice.

The Russian Geographical Society has prepared short notices on the progress of different branches of geographical science from 1875 to 1881, *i.e.* from the second to the third Geographical Congress. Three of them are printed: (1) "Aperçu des Travaux Hydrographiques"; (2) M. Bogdanow: "Aperçu des Recherches Zoo-géographiques en Russie"; (3) P. Matveiew and A. Stichinsky: "Aperçu des Études sur le Droit coutumier en Russie." Besides there are in preparation notices on botanical geography by M. Bataline, on geology by M. Alénitzin, and on Count Uvarow's work on the Stone Age in Russia, by L. Maikof. A. W. Grigorief and Dr. A. Woeikof will be the Russian official delegates to the third Geographical Congress. The absence of the celebrated Russian cartographers is much to be regretted; one of them, General Stubendorff, hoped to attend the Congress, but now it is known he will not be present.

The new number of the Geographical Society's *Proceedings* is remarkable for the excellent map of Khorasan and the neighbouring countries, in illustration of Col. Stewart's account of his journey and investigations in the Tekke Turkoman country and the region of the Tejend and Murghab Rivers. The map goes beyond Merv and Herat on the east and takes in the south-east part of the Caspian on the west. There is also an article on the recent journey of two Baptist missionaries from Vivi, by the north bank of the Congo, to Stanley Pool. Dr. Matteucci's great geographical achievement in North Central Africa and subsequent death in London are sympathetically referred to in the Geographical Notes. The Society's telegram of condolence to the Geographical Society at Rome appears to have been much appreciated there, as it has been reproduced in the Italian papers. One of the most interesting items in the present number is a letter from Mr. W. H. Dall, of the United States Coast Survey, on "The Chukches and their Neighbours in the North-Eastern Extremity of Siberia." The letter is written in reply to some strictures which Lieut. Nordgvist, of the *Vega*, addressed to the St. Petersburg Geographical Society, and which were noticed in the *Proceedings* for June.

The Berlin African Society has received further news from several German explorers in Western Africa. Dr. Pogge and Lieut. Wissmann were at Malange at the end of May, hoping to start early in June, and to reach Kimbundo at the end of that month. From Robert Flegel news are to hand up to June 4. The members of the station at Kokoma are occupied with scientific collections and the exploration of the environs. Dr. Stecker is trying to reach the Central African lakes from Abyssinia.

A new volume of travels by Mr. E. A. Floyer, F.R.G.S., &c., entitled "Unexplored Baluchistan, a Survey of a Route through Western Baluchistan, Mekran, Bashakird, Persia, Kurdistan, and Turkey," will be published during the autumn by Messrs. Griffith and Farran. Mr. Floyer was the first to explore the wild district of Bashakird; he contributed a paper on that little-known country to the Plymouth meeting of the British Association. Besides the narrative, which is full of interesting personal incident and adventure, the work will contain original illustrations, a map, vocabularies of dialects, lists of plants collected and tabulated, and observations, astronomical and meteorological.

Prof. Simony has published a list of the greatest depths of various Alpine lakes, which may interest our readers: Gmunden Lake, 191, Hallstadt Lake 125, Attersee 171, Mondsee 67, Wolfgang Lake 114, Achensee 132, Königssee 188, Lake of Constance 276, Chiemsee 89, Starnberg Lake 131, Lake Leman 309, Neufchâtel Lake 144 metres. The last-named four measures 92, 57, 589, and 240 square kilometres surface. The greatest depth of the northern part of the Adriatic is only 243 metres.

SCIENTIFIC SERIALS

The Journal of the Royal Microscopical Society, August, 1881, contains:—On some remarkable enlargements of the axial canals of sponge spicules and their causes, by Prof. P. Martin Duncan (plates 7 and 8).—On a blue and scarlet double stain, suitable for nerve and other animal tissues, by Dr. B. Wells Richardson. With the summary of recent researches, zoology, and botany, pp. 575 to 651; Microscopy, pp. 651-711.—Proceedings of the Society for June.

The American Naturalist for August, 1881, contains: The great crested fly-catcher, by Mrs. Mary Treat.—On the reasoning faculty of animals, by Joseph F. James.—On the progress of anthropology in America during 1880, by O. T. Mason.—On the manuscript Troana, by Cyrus Thomas.—The Editor's Table.—Some recent literature.—General notes and scientific news.

Proceedings of the Academy of Natural Sciences of Philadelphia, Part 1, January to May, 1881, contains: Dr. Jos. Leidy, Rhizopods as food for young fishes.—Thomas Meehan, note on treeless prairies; motility in plants; sexual characters in *Fritillaria atropupurea*, Nutt.—R. Arango, descriptions of new species of terrestrial mollusca of Cuba.—Rev. H. C. McCook, on the honey-ants of the Garden of the Gods. (This detailed memoir on the structure and habits of *Myrmecocystes melliger* is illustrated with ten plates.)—John A. Ryder, on the structure, affinities, and species of Scolopendrella. *S. gratiæ* is figured and described. An American specimen of what is presumed to be *S. notacantha* is also figured. The author places these strange insects in an order Symphyla, indicating that it has affinities to Thysanura; trachea are present. Henry Hemphell, on the variations of *Acmæa pelta*.—R. E. C. Stearns, observations on Planorbis (with many woodcuts).

American Journal of Science, August.—Method of obtaining and measuring very high vacua with a modified form of Sprengel pump, by O. N. Rood.—Geological relations of the limestone belts of Westchester county, New York; origin of the rocks of the Cortlandt series, by J. D. Dana.—New meteoric iron of unknown locality, in the Smithsonian Museum, by C. U. Shepard.—The relative motion of the earth and the luminiferous ether, by A. A. Michelson.—Observations on the light of telescopes used as night-glasses, by E. S. Holden.—Nature of dictyophyton, by C. P. Whitfield.—Observations on the comet, by H. Draper, C. A. Young, W. Harkness, L. Boss, and A. W. Wright.

Journal of the Franklin Institute, August.—Boiler explosion in Philadelphia in June, by W. B. Le Van.—Auchincloss's averaging machine.—Radio-dynamics II., by P. E. Chase.—The properties of air relating to ventilation and heating, by R. Briggs.

Annalen der Physik und Chemie, No. 8.—Experimental investigation of the tones which arise in passage of gases through slits, by W. Kohlrausch.—On the observation of air-vibrations in organ-pipes, by R. König.—On the conductivity of metals for heat and electricity (continued), by L. Lorenz.—On the application of photometry to the study of the phenomena of diffusion in liquids, by S. v. Wroblewski.—Experimental contribution to the theory of influence-machines, by W. Holtz.—On the development of polar electricity in hemimorphous crystals by variation of pressure in the direction of the unsymmetrically formed axes, by W. Hankel.—On the decomposition of water on platinum electrodes by discharge of Leyden jars, by F. Streintz.—On the resistance of polarised cells, by E. Cohn.—On the phenomena in Geissler tubes under external action, by E. Reitlinger and H. v. Urbanitzky.—Note on the maximum of temporary magnetism in soft iron, by C. Fromme.

La Nature, August.—The air-barometer, by Prof. Ferrini. The electro-photometer of Dr. Nachs.—On the electric phenomena of Canton's jar, by Prof. Righi.—On the origin of electricity in storm-clouds and atmospheric air, and on electricity in general, by Dr. Nachs.—On the direction of sounds and the object of double hearing, by Prof. Pinto.

Journal de Physique, August.—Researches on the capacity of polarisation (continued), by R. Blondlot.—Discharge of a condenser, and energy of telephonic currents, by H. Pellat.—On a new interrupter for induction-coils, by M. Deprez.—Note on the registering instruments of MM. Richard frères.

Bulletin de l'Académie Royale des Sciences de Belgique, No. 6.—Note on a new dolphin of New Zealand, by M. van Beneden.—A word on some new infusoria parasitic on Cephalopoda, by M. Fœttinger.—Study on the hypophysis of Ascidians and the neighbouring organs (second paper), by M. Julin.—Note on the fossiliferous Porphyroids met with in Brabant, by M. Poussin.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti. Vol. xiv. fasc. xii., xiii.—Researches on the phenomena of sense, motion, circulation, and respiration in hypnotism, and on their modification by æsthesiogenic agents, by Prof. Tamburini and Dr. Sepilli.—On some products of transformation of chinoline, by Prof. Körner.—Theorem on linear systems in projective measurements, by Prof. D'Ovidio.—Consequences of pachymeningitis and hematoma of cerebral membranes, by Prof. Sangalli.—Fasc. xiv.—On the small volcano of Querzola in the province of Reggio, by S. Taramelli.—On the resistance to passage of the voltaic current in an iron wire at different temperatures, by Dr. Poloni.

Rivista Scientifico-Industriale, July 1 and 15.—Determination of vapour density, by Dr. Valente.—Palæontological peregrinations in the Pliocene of Mount Falcone Apennino, in the province of Fermo (Marche), by Prof. Spada.—On determination of the electromotive force of the Voltaic couple by Fuchs' method, by Dr. Guglielmo.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 5.—M. Wurtz in the chair.—The following papers were read:—The direct-vision spectroscope applied to physical astronomy, by M. Zenger. One may (as before shown) compound refringent media whose index for the red ray A is less than that of crown glass or quartz, while the index for the violet ray H is much greater. The spectrum so produced is fan-shaped, and, with a single dispersion parallelepiped (two similar prisms with their refringent angles opposite), may be made of considerable length (25° and more). With one arrangement all the rays, except blue or red, may be eliminated, and the sun, *e.g.*, viewed in monochromatic light. M. Zenger specifies various combinations of quartz or crown glass with anethol, benzene, alcohol, &c. He obtains effects equal to those of the most powerful spectroscopes hitherto made.—Influence of nutrition on poisoning with strychnine, by M. Delaunay. Strychnine affects more quickly and intensely strong frogs than weak ones; frogs well fed than those which have been fasting; frogs that have been in vigorous exercise than those at rest; frogs that are exercised immediately after injection than those which are not; a frog hung by the leg than one hung by the head; an intact frog than one which has been bled; the right side of frogs than the left, &c.—Observations of Cruls' comet (*b* 1881) at Marseilles Observatory, with an equatorial of 0·26m. aperture, by MM. Borelly and Coggia.—Observations of Schäberle's comet (*c* 1881) in the same way and place, by M. Coggia.—Observations of Encke's comet, by M. Tempel. He observed it on the 21st ult. A letter from M. Loewy stated that M. Struve found it on the 24th (MM. Winnecke and Hartwig at Strasburg about the same time). The comet (according to M. Tempel) was large, but very diffuse, without nucleus or condensation towards the centre, and so, very difficult to observe.—On the light of comets, by M. Respighi. He considers we are not yet in a position to say that comets have a light of their own, due to incandescence of cometery matter. The discontinuity of the spectrum, and the bright lines and bands, may arise from reflected light as affected in traversing the gases and vapours of the comet; the same cause as affects the spectrum of the sun when near the horizon. Only the phenomenon is exaggerated in comets by reason of the enormous thickness of the absorbent layers, their richness of chemical composition, and the weakness of the light they reflect to us.—On observations of meteors from July 25 to 30, 1881, by M. Cruls (Rio). More than 90 per cent. of the meteors seemed to radiate from near Fomalhaut. The horary average increased rapidly between the evening and morning hours, and there was a remarkable recrudescence shortly before sunrise. It would thus seem that the stream of meteors moves in opposite direction to the earth. This is corroborated by the fact that the morning meteors, especially after 5 a.m., all moved with great velocity, and were very brilliant. They were all sensibly displaced in the plane of the ecliptic; their direction is probably very little inclined to this plane.—On ferruginous carbonated waters, by M. Ville. Neutral alkaline carbonates precipitate such water immediately; neutral alkaline earthy carbonates also have this effect, but more slowly. Alkaline and alkaline-earthy bicarbonates do not alter ferruginous water. Chlorides and sulphates sensibly retard the decomposition of ferruginous water in air. The disturbing influence of neutral alkaline carbonates may explain the relation between the richness of ferruginous carbonated waters and the presence of these saline compounds. The action of neutral carbonate of calcium explains the existence of considerable beds of limonite in calcareous strata.—On absorption by the vesical mucus, by MM. Cazeneuve and Lépine. The sound bladder absorbs the normal elements of urine. Certain toxical or medicamentary substances (*e.g.*, sulphate of strychnine) are not absorbed.—On experimental tuberculosis, by M. Brunet.

EGYPTIAN EXCAVATIONS AND MUMMIES

THE recent excavations in Egypt have been productive of great results to archæology and the history of Egypt. One site, which has yielded unexpected additions to the early period of the country, has been excavated on scientific principles under the direction of M. Maspero, the present superintendent or director of the Archæological Department. It is his intention to open the whole group of unexplored pyramids, in order to find the sequence of monarchs of whom they were the sepulchres, and to discover any inscriptions with which they may have been decorated. An examination of the whole group of pyramids indeed was formerly made by J. Shay Perring, C.E., at the expense of Col. Howard Vyse, who spent a fortune in pyramidal researches; but the excavations of Perring were chiefly devoted to the examination of three great pyramids of Gizeh, those of Cheops, Chephren, and Mycerinus, and although he examined the whole group in the scientific manner of an engineer, by some fatality he appears not to have penetrated into the interior of the smaller ones, which are now in process of examination by M. Maspero. The conviction which that *savant* has arrived at is that these pyramids are arranged in symmetrical groups, each group holding the remains of the monarchs who followed each other in chronological succession. The group just discovered consists of three pyramids at Sakkara, of small dimensions, lying to the N. and E. of the step-shaped pyramid, and on the road to the Serapeum, the sepulchres of three monarchs of the sixth dynasty, Ra-meri or Mira, whose name was Pepi or Phiops, a king who is said to have reigned 100 years all but an hour; his successor, Merienra, named Har-em-saf, or Ta-em-saf, and a king called Una. They seem all to have been constructed on the same principle, having inclined entrances leading to sepulchral chambers with pointed roofs, the walls of the passages and chambers covered with hieroglyphs coloured green, the ceilings of the sepulchral chambers with pointed roofs on which were stars in white upon a black ground, indicative of the hours of the night. The inscriptions of these chambers are of interest purely mythological, no historical fact or allusion being mentioned in them, but their contents consisting of prayers similar to those in the Book of the Dead, or Ritual, and chiefly referring to the myth of Osiris and Hades, especially the identification of the kings with Osiris as the son of Nut and Seb, and his following the course of the constellation Orion, rising and setting with that constellation, allied with the star *Sebt*, or Sothis, and the progress of the king to the *Aahlu* or Egyptian Elysium, and in the account of the Island of the Fields of Ho-tep, or Peace, recalling to mind Eden, mention is made of a tree of life. In the Pyramid of Pepi, the Phiops of the sixth dynasty, who is said by the history of Manetho to have reigned 100 years all but an hour, and who must consequently have ascended the throne quite a boy, was found the remains of a sarcophagus of black and white granite of unfinished work, which had been broken, and another in the south-east corner of the chamber of the same material, which had been let into the masonry. In the vicinity of this sarcophagus on the west side between this and the wall was found amidst a heap of rubbish remains of dresses and mummy bandages varying from yellow to dark brown of extreme fineness; of the mummy itself an embalmed hand in good condition was only found, and even this may be considered remarkable, as the bodies of the earlier period were only dried, and not embalmed, and generally fall to pieces when exposed to air. The pyramid was indeed small, considering the long reign of Pepi. The Pyramid of Merienra, or Har-em-saf, which resembled in general character that of Pepi or Phiops, had two sarcophagi of red granite close to one another, the cover of one removed and hidden under blocks of stone. The other held a body mummied, which was that of the king; it had been anciently plundered of its ornaments, but embalmed with the greatest care, the skin well preserved, the traits of the countenance distinct, the eyes closed, the end of the nose fallen in, the stature of medium height, and the limbs youthful. This king was the successor of Phiops. The third pyramid of the group was of Noferkara or Nephercheres, but no details of the inscriptions have as yet been published, although they probably refer to the Osiris myth, like the others. The details of the size of coffins and mummies of this pyramid are still wanting. Each pyramid had a special name: that of Pepi was called Mennefer, that of Ha-rem-saf was Shanefer, that of Noferkara also Mennefer. Compared with the great Pyramids of Gizeh, they are far inferior, but the inscriptions in them offer an interest greater than that of the plain Gizeh Pyramids. The only question is whether the mummies found in them are contemporaneous with the sixth dynasty, which appears most probable, or subsequent usurpations, of which there is no monumental or inscribed evidence.

The next remarkable discovery is that of the thirty-nine mummies, several of kings, in a subterraneous well or pit not very far from the edifice of the Deir-el-Bahari. This remarkable structure, consisting of a temple on a platform with chambers let into the solid rock, had been published by Marriette Pasha, and had been suspected by Brugsch Bey to be the site of the sepulchres of the early monarchs of the eighteenth dynasty. The temple itself had been commenced by the queen Hatasu or Hasheps, daughter of Thothmes I. and wife of Thothmes II., and its sculptures commemorated the expedition made by that queen to Punt or Somali, the treasures brought from thence in gold, silver, frankincense, besides trees of that material, besides giraffes, cynocephali, large dogs. Besides which they give representations of the inhabitants and of the Egyptian fleet which descended the Red Sea on the voyage of amity or discovery promoted by the Egyptian queen.

In the well or pit of the Deir-el-Bahari, which was formed of bricks of conical shape stamped with inscriptions, on which could be traced the titles of the high priest of Amen-ra thus used by the monarchs of the twenty-first dynasty, were found the coffins, mummies, and other objects which appear to have been there deposited in the reign of Herhor, first monarch of the twenty-first dynasty, and of another king, Panetem or Pinotem, of the same dynasty. The cause of the removal of the mummies deposited in the Theban sepulchres, such as the El Assasif and the Biban-el-Molook, is stated on some of the wraps of the mummies to have been the apprehension

of a foreign invasion, and that possibly of the Assyrians, whose arms had made great progress in Central Asia. According to Brugsch Bey the twenty-second dynasty was Assyrian, and he identifies the name of the monarch with that race; but at all events they were never Assyrian monarchs, such names as Shashanq or Shishak, Namrutha or Nimrod, not having been found in the Assyrian annals, although Uasarkan or Sargon, and Takelloth or Diglath may correspond with Assyrian kings.

From the El Assasif had been removed the mummy of Taakan, also known as Skanenra, which was formerly deposited at the Drah Abu-el-Neggah with its three inscribed coffins, and which was intact at the time of Rameses IX. about B.C. 1150. It was in his reign that the quarrel of the Egyptian kings with the Shepherd Kings commenced, and he is mentioned in the celebrated Sallier Papyrus. The mummy of Aahmes or Amosis I. in three plain cases was also found amongst the coffins, but it is not known where this king was buried; as he succeeded Skanenra, his tomb was probably somewhere in the vicinity. The mummy of Aahmes Nefertari was also found, it is said, in three cartonages with paintings on a white ground. Another queen, Aahhotep, daughter of the King Aahmes, was also found, and it will be recollected that this was the name of the queen whose mummy and coffins, and gold and silver jewellery, and arms were discovered by fellaheen at the Biban-el-Molook, a few feet below the surface. She was wife of Kames and mother of Aahmes, while the queen of the Deir-el-Bahari was the wife of Amenophis I. The mummy of Amenhotep I. or Amenophis was found in a wonderful state of preservation, painted and varnished, and with wreaths of flowers so exquisitely preserved that they retain all their colour like recent flowers kept and pressed between the leaves of books. These flowers, it will be remembered, are above 3000 years old, and their preservation is probably due to their having been buried in hot sand, a mode still in use in Palestine, by which means botanical specimens retain their colour for a long time unchanged, a process perhaps known to the ancient Egyptians, although wreaths and flowers, even of the Roman times, from Egypt are brown and semicarbonised. The tomb of Amenophis I. is mentioned as at the Drah Abu-el-Neggah in the Abbot Papyrus, and the body transported thence of Thothmes I., his son; the mummy case, considerably mutilated, was only found, and this had been appropriated by Pinotem. The mummy of Thothmes II., in three mummy cases, was likewise discovered. That of Thothmes III., the great and warlike monarch of the eighteenth dynasty, was found in a single coffin much mutilated, his body broken into three pieces and rifled in ancient times, but with an inscribed ritualistic linen roll said to prove the identity of the mummy. Of the other personages of the eighteenth dynasty were the mummies and coffins of the Prince Saamen, the Princess Satamen, a princess and king's sister, but unmarried, named Hanta-em-hu; and a similar royal sister and queen named Me-han-ta-emhu, child of Hanta-ena-hu, had been removed at the time of the twenty-first dynasty; another unmarried queen-sister named Miramen, and Nebseni, a priest or flamen of a Pharaoh. All these coffins of the eighteenth dynasty have a certain similarity with each other. Those of the nineteenth are Rameses I., whose tomb and sarcophagus are at the Biban-el-Molook. There is some uncertainty in the different accounts which have come to hand whether there are three coffins or one, and if the mummy was deposited at the Deir-el-Bahari. The mummy of Seti I., whose tomb is in the Biban-el-Molook and alabaster sarcophagus in the Soane Museum of London, is well preserved in one wooden coffin; the mummy of one of the Ramessids, apparently the twelfth, not the second, as reported, in a plain coffin, the features not aquiline, but the shroud, covered with lotus flowers, looking remarkably fresh; this also came from the Biban-el-Molook. These mummies, it is stated, were removed under apprehension of a foreign invasion. Then follow the cases and mummies of the twenty-first dynasty. The queen, Notem, mother or wife of Herhor, of whom there is a papyrus in the British Museum, exhibited by H.R.H. the Prince of Wales, in a badly-preserved but inlaid coffin; Panotem or Pinotem, high-priest of Amen, in three coffins of the style called *richi* by Marriette, and gilded faces; he was, besides high-priest, a *saten sa Kush*, Prince of Cush or Æthiopia, according to the inscription in Lepsius' *Königsbuch;* the queen, Ramaka or Makarra, who assumed the same prenominal title as Hatasu of the eighteenth dynasty, who is in three coffins with the youthful queen, called the "lady of the two countries," or absolute queen-heiress, embalmed in a sitting posture, either having died in a fit or at her birth, and named Mutemhat; the king, Pinotem II., hastily deposited in the coffins of Thothnes I., the mummy has been partially unwrapped and the features exposed, which have a singular resemblance to those of Voltaire, with a sarcastic or satiric smile or grin, a peculiarity also found on a hieratic papyrus ritual in the British Museum, probably of the same period; the queen-mother, Hantau, whose ritual had found its way to the Boolak Museum prior to the discovery; in three cases, the prince Masaharuta, son of Pinotem II. in the same; the queen Asemkheb or Hesemkheb, in as many cases, who appears to have been the wife of Menkheperra; another princess called Nasikhonsu; Tet-ptahaufankha in an appropriate coffin, and four other priests and functionaries. Several other objects were found in the pit: a leather tent embroidered with names, boxes with royal names, boards with inscriptions, and five rituals of the monarchs of the later dynasty; but the whole of the details—amulets, inscriptions, and style of art—cannot be known until the mummies are unrolled and all peculiarities carefully examined, for this remarkable find will afford invaluable data for Egyptian archæology, especially the sepulchral division.

TWO SPIDER BOOKS

The Spiders of Dorset, with an Appendix containing Descriptions of those British Species not yet found in Dorsetshire. By the Rev. Octavius Pickard-Cambridge, M.A., C.M.Z.S., &c. From the *Proceedings* of the Dorset Natural History and Antiquarian Field Club, edited by Prof. James Buckman. (Sherborne: L. H. Ruegg, pp. 1-625, with 6 plates, 1879-1881, 8vo.)

Studi sui Ragni malesi e papuani. Per T. Thorell. III. Ragni dell' Austro-Malesia e del Capo York, conservati nel Museo Civico di Storia Naturali di Genoa. Pp. 1-720. 8vo. (Genoa, 1881.)

IF we take down part 2 of vol. i. of the twelfth edition of Linné's "Systema Naturæ" (1767) and refer to that marvellously incongruous order *Aptera*, in which the

old naturalist contrived to group together nearly all the Arthropods known to him and which agreed almost solely in the one point of the non-possession of wings, we find under the genus "*Aranea*" only 47 species indicated, and of these only 9 are from outside Europe. In the second edition of the "Fauna Suecica" (1761) we find 33 species indicated for Scandinavia. Thus six years later all the spiders known to Linné from outside his native country amounted to 14 species! At the present time 518 species are recorded as British, and a still almost unexplored region of the Eastern Archipelago has contributed nearly as many from the researches of one or two naturalist-travellers, with whom spider-collecting was certainly not considered of first importance. And yet, notwithstanding the vast and rapid strides that arachnology has made within the twenty years past, the number of workers is still small. The subject is not always an attractive one to naturalists, and is often repugnant to non-naturalists, with whom a passion for collecting or studying spiders is seldom associated with respect for the naturalist thus smitten. But all this is rapidly changing, and no two men have done more to bring this about than the authors of the books noticed below.

In vol. xxi. p. 273, we noticed vol. i. of Mr. Pickard-Cambridge's work; vol. ii., completing it, is now before us. The whole is dedicated to John Blackwall, and the second volume must have appeared about the time of the decease of that venerable naturalist. A postscript notices some species new for the county or for Britain, and there are additional remarks on senses and economy, in which "sight," "touch and hearing," "power to utter sounds," "venom," "modes of forming snares," &c., are severally alluded to. With regard to "venom," the author expresses his firm belief that the bite of the common garden geometric spider (*Epeira diadematа*) is attended by the emission of a poisonous fluid, sufficiently strong to cause visible effects on the skin of his young son, but without effect upon his own. He now agrees with the conclusion that currents of air play a great part in enabling spiders to carry their lines across from one object to another, although previously he was of opinion that the lines were carried across by the spiders themselves. As we remarked when noticing vol. i., it is a pity the author did not intercalate the descriptions of those British species not yet found in Dorsetshire amongst the others, instead of placing them in appendices at the end. This would have vastly increased the usefulness of what is still a most useful work, and while not destroying its local intentions (as indicated by the title) would have rendered it more distinctly a *Manual of British Spiders*, for such it really is. With it and Blackwall's magnificently illustrated Ray Society monograph before him, no student of our spider-fauna should be at a loss to determine, with approximate certainty, any species he may come across. The six plain plates are excellent, engraved from the author's own drawings, and representing many of the principal genera, with copious details. The index is full. The author recognises 518 species of spiders as inhabiting the British Isles, of which 373 have been found in Dorsetshire. The distribution of these amongst the several families is strikingly unequal. Thus we find three families represented by only one species each; another by only three species. On the other hand the *Therideides* claim 267 species, the *Drassides* 56, the *Epeirides* 32, and so on. Possibly this is the first time that any thoroughly local society has undertaken to bring out a manual of a large group of British animals; so much the more to the credit of the Dorset Society for initiating so laudable a scheme. Their undertaking, so well concluded, is not of local (or even British) interest only, but will have to be considered by every European student of *Arachnida*.

In Dr. Thorell's bulky memoir (which forms vol. xxii. of the *Annali del Museo Civico di Genoa*) the author continues his studies on the Spiders of the Eastern Archipelago. The descriptions are worked out with his well-known detail and accuracy. Most of the materials result from the exploring voyages of D'Albertis and Beccari, and the flourishing society under whose auspices the volume is published deserves the highest credit for the promptness with which it is making known to the scientific world the riches acquired during the voyages of these renowned travellers. The descriptive portion is preceded by a bibliographical sketch of what was previously known from the regions, with an analytical and comparative examination of the arachnid fauna generally, still further subdivided in a series of tables at the end; 317 species are noticed as in the collection (of which 173 appeared to be new to science), viz. 252 from Austro-Malesia and 82 from Cape York, but 505 are recorded for the whole of that part of the globe, divided as follows:—*Orbitelariæ*, 162 species; *Retitelariæ*, 38; *Tubitelariæ*, 31; *Territelariæ*, 10; *Laterigradæ*, 84; *Citigradæ*, 29; and *Saltigradæ*, 151. Some idea of the riches of the fauna in this particular respect may be gathered from the fact that no less than eighteen species of the extraordinary genus *Gasteracantha* are described. We cannot resist a few words of admiration at the manner in which the publications of this Italian society are got up, the more so as the printing is done at the Deaf and Dumb Institute of Genoa (Istituto Sordo-Muti). Paper, typography, and editing alike leave nothing to be desired.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Oldest-known Insects

I MUST ask your permission to correct the errors into which your correspondent, Dr. Hagen, has fallen respecting the Erian (Devonian) beds near St. John, New Brunswick, holding certain fossil insects described by Dr. Scudder.

The Dadoxylon sandstone and Cordaite shale of the vicinity of St. John have been studied not only by myself, but by so good geologists as Prof. Hartt, Prof. Bailey, and Mr. Matthew, and by the officers of the Geological Survey of Canada; and their stratigraphical relations have been illustrated by maps and sections, not only in my "Acadian Geology," but in the *Reports* of the Geological Survey, more especially those for 1871 and 1875. They have, besides, been thoroughly exposed and ransacked for fossils by expensive quarrying operations undertaken by the Natural History Society of St. John, and their plants have been described and compared in detail with those of the neighbouring Carboniferous formations in my Report "On the Devo-

nian Plants of Canada," and subsequent Reports on the plants of the Lower Carboniferous and Millstone Grit formations (Geol. Survey of Canada, 1871 and 1873). In these circumstances it seems strange that the received conclusions as to their age should be termed "simple negation not supported by facts," and regarded as of no scientific value in comparison with the mere assertion of a gentleman who has no knowledge whatever of the stratigraphy of the region, and with the "authority" of Dr. Heer, who is no doubt an excellent authority on certain departments of European palæobotany, but who has not seen the beds in question, nor, so far as I am aware, studied their fossils.

The beds referred to, like the Devonian generally in Eastern Canada, underlie unconformably the lowest Carboniferous beds, a circumstance due apparently to the extensive igneous action which closed the Devonian period in this region, giving origin to masses and dykes of intrusive granite, and disturbing and partially altering the strata of Devonian and greater age, the materials of which have contributed to the Lower Carboniferous conglomerates. There is thus no question here as to any transition between Devonian and Carboniferous, and the beds holding the plants and insects are stratigraphically pre-Carboniferous.

The Lower Carboniferous beds, succeeding to the Devonian formation, and developed to the eastward of St. John, hold the characteristic flora of the Horton series, or Lowest Carboniferous, equivalent to the Calciferous or Tweedian formation of Scotland. In succession to this we have the flora of the Millstone grit, of the true Coal-Measures, and of the Permo-Carboniferous or Lower Permian. All of these have been explored and their plants catalogued and described in my own memoirs or in the reports of the Geological Survey, and it has been fully established that the flora of the Devonian beds is characteristic and distinct from any of these sub-floras of the Carboniferous.

The plants of the Cordaite shales are not only distinguishable from those of the Carboniferous found in their vicinity, but the assemblage includes forms like *Psilophyton* and *Archæopteris*, which are characteristic of the Devonian, and are not found in the Carboniferous elsewhere in America. In the Devonian of Northern New Brunswick some of these plants are associated with fishes of the genera *Cephalaspis*, *Pterichthys*, &c., well-known Devonian types.

For additional information as to the geological relations of the St. John plant beds and notices of new species, I may refer to my paper on "New Erian Plants," in the *Journal* of the Geological Society of London, vol. xxxvii., May, 1881. This paper Dr. Hagen had probably not seen at the time when his letter was written.

The particular fern in question, *Pecopteris serrulata* of Hartt, has been fully described, first by Prof. Hartt, and subsequently by myself, and its distinctness from *P. plumosa* pointed out.[1] The criticism of Dr. Hagen, as to its not appearing in the sectional lists, and still being called by me a common fern, is based on a mere accident, which I could easily have explained to him. The plants referred to as found in each layer in the detailed section are those originally described by me from these beds. Some species, subsequently recognised and described by Hartt, were not included in the sectional lists, and were referred to only in a note, because I had received no information from Prof. Hartt as to the particular layers in which they were found, though I knew that some of them were by no means uncommon, from the number of specimen obtained. Dr. Hagen criticises my figure of the species, but that does not affect the question, as I have compared the specimen on the slab with *Platephemera* with the original specimens in my collection. My figures, however, show fairly the general form of the frond; and there is also a magnified figure of a pinnule, showing the venation, which should enable any one to recognise the species, and with the aid of the description to distinguish it from *P. plumosa*.

With regard to the "Ursa stage" of my respected friend Dr. Heer, founded on a little known and apparently exceptional locality, I have always objected to its being made a standard of comparison for the thoroughly worked and widely distributed Devonian or Erian rocks of North America. I gave some reasons for this in a paper sent to the Geological Society of London shortly after the appearance of Dr. Heer's memoir, an abstract of which appears in the *Proceedings* of the Society. It will be sufficient to say here that the grounds on which Dr. Heer refers the Devonian of New Brunswick to the Ursa stage would apply to the Chemung, and even to the Hamilton formations of the New York series.

[1] "Acadian Geology; Report on Devonian Plants." *Canadian Naturalist*, 1881.

The great richness of the Devonian of North America in fossil plants is a very remarkable geological fact, which I regret to say has hitherto far exceeded the means available for its adequate illustration. I hope, however, to remedy this to some extent on the occasion of the meeting of the American Association in Montreal in 1882, when my whole collection of Erian plants, together with those illustrating the several stages of the Carboniferous, will be exhibited in the new Peter Redpath Museum, and will show more fully than has been hitherto possible the progress of the American flora from the Silurian to the Permian. It will be a great pleasure to me if any palæobotanists who are sceptical as to the magnitude of the Devonian flora will avail themselves of this opportunity to judge for themselves and to form their own opinions as to the affinities and relations of the species.

McGill College, Montreal, September 2 J. W. DAWSON

Sound-producing Ants

I AM glad to see my statement in NATURE, vol. xxii. p. 583, verified by Mr. H. O. Forbes, from Sumatra, and now inclose a few ants of another kind that make this peculiar tapping or scratching sound, though not in the same system of taps as those before noted, and that was thus—

- - — — - - — — - - — — - - —

i.e. three taps in unison and a pause of about a second, the taps of equal duration. The ants inclosed make a series — — — — — — ··· that dies off and does not seem repeated unless the exciting cause again acts, when they again start in beautiful unison. How they so correctly start together in all cases of - - — — or the — — — — - - — — and keep each tap in time, is really wonderful. White ants make similar tappings, but not in rhythm as far as I know, and they use it to call or warn. These little black ants cannot be heard by us unless the material they are on is sensitively sonorous. Happening to place a tumbler on a sideboard lately in the dark, I was startled to hear this — — — — — — — arise from a sugar-bowl. I repeated it, and the noise at once convinced me that it was ants. On getting a light I found a sheet of writing paper had been laid on the bowl, and was covered by them; the glass alone was useless, I found. S. E. PEAL

Asam, July 6

[The ants sent are apparently "workers" of a species not larger than a small British *Myrmica*.—ED.]

Wasps

A COUPLE of weeks ago I found on my window-pane a large black wasp holding in its mandibles a plump spider of about an eighth of an inch in diameter. I placed the wasp under a bell-glass and set it on my desk, where I could readily watch for further developments. Finding itself in captivity, the wasp dropped its booty and spent some time in trying to find a way of escape. Coming at length to a state of rest, it espied the spider and sprang upon it with tiger-like fierceness. Seizing it and raising itself up to its full height, the wasp brought its posterior under and forward with a quick motion, and gave the spider, two or three thrusts with its sting. Assured that the spider was dead, the wasp proceeded to roll it over and over, rapidly working it up into a globular mass. This done it started to fly away; but, foiled in the attempt, it dropped the spider, which was for some time apparently forgotten. This whole operation I saw several times repeated during the two days of my observations. Being called away from home for a few days, I was curious on my return to ascertain the results of my experiment. I had taken the precaution at the first to place under the bell-glass a small dish of clean water, to which the wasp had helped itself freely. I found the wasp dead; but not the least morsel of the spider had it eaten. My conclusions are: (1) that the wasp died of starvation; (2) that the spider was intended, not for its own food, but for that of its young in their larval state. In confirmation of this I have broken open several of the finished cells of these wasps, and found them filled with pellets made of portions of spiders, flies, and worms. Only yesterday a fine opportunity was afforded me for further observations in this direction. One of my flowering vines is infested with a green worm—the larva of the yellow butterfly. I discovered a bronze-and-yellow wasp standing on the edge of a leaf of this vine, holding fast to one of these worms of twice its own size. The worm was dangling in mid-air, and the wasp endeavoured laboriously for a long time to pull it up on the surface of the leaf.

Failing in this, with a dexterity worthy of the Knight of the Shears it cut the worm in two, letting about three-fourths of it fall to the ground. The remainder was then easily dragged to the surface of the leaf, where the wasp spent some fifteen minutes in cutting down, trimming, and reducing it to a globular mass of about an eighth of an inch in diameter. Then resting for a few minutes, and taking a fresh hold of its booty, it flew briskly away. J. T. BROWNELL

Lyons, N.Y., August 13

Treatment of Hay Fever

SOME years ago Prof. Helmholtz, in a letter to you, gave an account of a remedy he had found for "hay fever." This was simply to treat the part of the nose, which seems to be the seat of the trouble, with sulphate of quinine solution by pouring it into the nose with a pipette, while lying on a sofa with the head turned upside down. Having had the most enjoyable part of summer destroyed by hay fever ever since I can remember, I have tried every remedy I have heard of, including internal doses of arsenic, and I have found them all to fail. Prof. Helmholtz's method only gives me relief for ten minutes or so, and cold water does the same. I have tried solutions of sulphate of zinc and tannin, and many other astringents, but all to no purpose. As many others knew that I was experimenting upon myself in this matter, I have had several patients trying all the remedies that I have tried, and I can therefore say with certainty that no remedy yet published will cure hay fever. I have however succeeded in finding a method which is a really effectual cure, and as I know that many are rendered miserable during the most enjoyable part of the year, I hasten to give them the benefit of the result of my inquiries. One thing which misled me was that my eyes were often very much inflamed and pained during an attack, and I often tried remedies for my eyes (which have sometimes gone wrong when I had no hay fever) when they were only affected in sympathy with my nose. I found that the only thing required was to prevent the entrance of the pollen grains into the nose. When there are not many in the air, as during or after rain, it is simply necessary to stop the nose with a spring clip. I have used a piece of brass or steel ribbon bent double, and having only sufficient spring to close the nostrils without undue pressure. This causes the patient to breathe by the mouth, but one soon gets accustomed to the inconvenience. I found that to stop the nostrils with cotton wool was far too irritating, especially as those afflicted with hay fever are so owing to the tenderness of the internal coating of the nose. When going amongst hay a further precaution must be taken, viz., plugging the ducts from the eyes. I used for this purpose dumb-bell shaped pieces of glass, which are easily slipped into the ducts, and can be removed when wanted. Thus protected, any one who is troubled by hay fever can go into the camp of the enemy and stir up hay in a field with as much impunity as one not troubled with this "sixth sense." The season for hay fever is nearly passed now, but I hope that the publication of this note will be the cause of relief to many during next summer, and on that plea I ask its publication in your valuable journal, and I hope that medical men in the South of England, where hay fever is common, will give it a trial and report upon it next summer. In Scotland hay fever is practically unknown. J. B. HANNAY

Red Rainbows

PROF. S. P. THOMPSON'S letter (p. 459) makes me recall that when on September 2 last year I crossed Wales westwardly from Hereford, on a fine sunny day, the train ran into a misty shower after 6 p.m. at Machynlleth, and out of it as we neared the viaduct at Barmouth. The sun had been obscured for some time, when it suddenly shone out through a chink between sea and cloud, causing in the east a very beautiful red rainbow. Like Prof. Thompson, I was under the impression that the phenomenon was of no uncommon occurrence, so did nothing more than note it in my diary. HENRY MUIRHEAD

Cambuslang, September 16

Infusorial Parasites on Stickleback

ONE day in June, when examining a very small stickleback under the microscope, I was surprised to find it infested by numbers of infusoria, evidently parasitic upon it. This led me to examine others from the same water, viz, a pond very rich in infusorial life generally, as also specimens from the river close at hand. Every specimen from the pond was similarly attacked, while none of those from the river were so. The parasite is apparently *Trichodina pediculus*, which is stated to be parasitic upon *Hydra vulgaris*. Want of literature on the subject has prevented me from following the matter up, but it seems that I have found, if not a new species, at least a new host for a known species. I shall be glad if any of the readers of NATURE can give me any information on the subject. N. H. POOLE

Charterhouse, Godalming

Photographing Diffraction Rings—Optical Phenomenon

THE peculiar character of the photographs of an opening to the sky in the dark Cyclopean gallery at Tiryns, to which Mr. W. J. Stillman calls attention (NATURE, vol. xxiv. p. 262), finds an obvious explanation in the well-known optical phenomenon of diffraction rings, produced when a beam of light is transmitted through a small circular aperture, and viewed by means of a lens. Had your "Cecropian" correspondent examined the image of the illuminated opening by the assistance of a lens, the phenomenon of concentric coloured rings would, doubtless, have been recognisable to the eye. Hence the only point of interest in the phenomenon observed by Mr. Stillman is the significant fact that in securing the fleeting images of the rings on the gelatine plate—the actinic rays being alone effective—alternate dark and bright concentric rings are produced, as in the case of homogeneous or monochromatic light, instead of the coloured rings seen by interposing a lens between the aperture and the eye. In other terms, the impressions on the gelatine plate being due to the action of the monochromatic actinic rays, the theory of diffraction shows that the concentric rings should be alternately dark and bright. This is an important circumstance in the applications of photography to such investigations.

Berkeley, California, August 16 JOHN LE CONTE

A Primitive Diving-Bell

IN NATURE, vol. xxiv. p. 201, it is stated that Herr Budde has found a description of a primitive diving-bell in a work of Bartolmi, 1674. The inventor appears to have been Franciscus Kesler, 1616. This description of Kesler's diving machine will also be found, together with representations of the same, in Schwenter's "Delicize Physico-Mathematicæ," 1636, a very rare and curious volume; so rare indeed that it is stated in *Cosmos*, January 27, 1860, "it is not to be found in the Imperial Library, nor in any of the public libraries of Paris." J. van Lennep, in *Notes and Queries*, December 15, 1850, p. 503, says "there is a Dutch translation of Schwenter, 1672; of this rare volume I fortunately possess a copy." N. S. HEINEKEN

Sidmouth, September 11

ITTAVIO LAUDI.—Messrs. Trübner, publishers, London, might be able to help you to get copies of the Chinese translations mentioned in Mr. Fryer's articles on "Science in China."

FREDERICK CURREY, M.A., F.R.S.

THE late Frederick Currey, whose death was announced in last week's NATURE, p. 475, was born at Eltham on August 4, 1819, educated at Eton and Trinity College, Cambridge, there obtaining a scholarship, and attaining his B.A. in 1841; three years later he proceeded to M.A., and was called to the Bar, afterwards practising as conveyancer and equity draughtsman.

His first public performance as a scientific writer was a translation of Schach's "Das Mikroskop" in 1853, a second edition of which was called for within two years. In the *Microscopical Journal* for 1854 he published some observations on two new fungi, and by the same channel he afterwards communicated several papers, chiefly on the obscure points in the reproduction of the lower cryptogams. The Greenwich Natural History Club was established in 1852, Mr. Currey being one of the earliest members, and the next year he read a paper on the

"Fungi of the Neighbourhood of Greenwich," which was printed in the fifth volume of the *Phytologist*. In 1857 a committee of that Club was appointed to draw up a report on the flora of the district; Mr. Currey was chosen its chairman, and drafted the report, which enumerated 395 fungi. In that year he contributed a paper to the Royal Society, which was printed in the *Proceedings*, On the Occurrence of Amorphous Starch in a Tuberaceous Fungus, a point of much interest, as starch is rarely found in fungi. He was elected Fellow of the Linnean Society in 1856, and in 1858 Fellow of the Royal Society also; in 1860 he was appointed secretary of the former society in succession to Mr. J. J. Bennett, a post which he held until 1880, when he relinquished that office and acceded to the less arduous duties of treasurer, retaining that appointment until his death. In 1862 the Ray Society issued a translation, with considerable additions, from Hofmeister, entitled "On the Germination, Development, and Fructification of the Higher Cryptogamia," a task which Mr. Currey undertook in 1859; the following year he edited a second edition of Dr. Badham's "Esculent Funguses of England," in which he made as few alterations as possible. Several papers on mycological subjects appear in the *Transactions* of the Linnean Society, which will be found in the "Catalogue of Scientific Papers," under his name, his last contribution being, "On a Collection of Fungi made by Mr. Sulpiz Kurz," in 1876.

By his death the Linnean Society has lost an experienced officer, and its members a valued friend whose place it will be hard to fill.

THE AMERICAN ASSOCIATION

THE thirtieth meeting of the American Association for the Advancement of Science commenced at Cincinnati on August 16. Always a hot place in summer, the temperature at Cincinnati during the past two months has been at intervals unusually high, running above 100° for several days together. This and the fear of its recurrence no doubt induced many to stay away who would otherwise have been present. However, a goodly number —over 400—of new members were enrolled, and many papers of interest were read. Some of the visitors from the Eastern States were amazed to find that Cincinnati was not a little backwoods town, but a city deserving in many ways the title she claims, "The Queen City of the West." The ignorance of many of the inhabitants of the Eastern States in regard to the West is only equalled by the ignorance of Europeans in regard to America generally.

The citizens of Cincinnati exerted themselves to welcome their guests, and did it well. Their bodily wants were amply supplied, and this, to those coming from a distance and being strangers, was a matter of no small moment. Visitors known or bearing introductions were in very many cases entertained privately, and a free lunch was provided by subscription for all members daily from 1 to 2.30 p.m. The Western Union Telegraph Company, whose wires extend over almost the whole Union, gave the members the use of their lines for communication with their families, free of charge, at whatever distance they might be situated. Connection was made by telephone between the hall of meeting and the Central Telegraph Office, and between the various rooms in the building, so that it was possible to send a message without leaving the building—to ask, for example, what paper was being read in any other section. The City and Suburban Telegraph and Telephone Companies also extended the same privileges to members of the Association. The various Express Companies offered to convey light parcels containing specimens for them, free of charge, between their homes and the place of meeting, and heavy ones at low rates. Of course there was a post-office and a parcels office in the hall, with convenience and materials for writing. There was however a little deficiency in finger placards to direct strangers over the great building in which the meetings were held—the new music hall.

Besides the above, an excursion was arranged for Saturday afternoon to the Zoological Garden, one of the best in the country, and capable, if well supported, of becoming *the* best. Free transportation through the streets by the horse cars was provided, and a sumptuous repast prepared for the visitors before leaving. In the same way the Anthropological Section and others were taken out to Madisonville, about ten miles from the city, on Monday to see a prehistoric cemetery recently discovered, from which several hundred skeletons, uncounted arrow-points, animal bones, horns, and teeth, and pieces of pottery have been exhumed during the past two years. The train stopped at the place to set them down, and again on its return to take them up. After the adjournment of the meeting an excursion was arranged to the Mammoth Cave, about 150 miles distant, and another to Chattanooga, about 300 miles over the new Southern Railway, both free so far as the travelling was concerned.

It will be evident that Cincinnati did her best to entertain her scientific visitors, and the latter carried away pleasant and lasting impressions of the city where the fifth and the thirtieth meetings of the Association were held, the latter having been one of the most successful in its history. E. W. CLAYPOLE

Another correspondent writes :—

The Cincinnati meeting proved to be one of the best ever held by the Association. In attendance of members it was much surpassed by the Boston meeting last year, which reached the phenomenal number of 997; the number at Cincinnati was about 550, being more than double that at any previous meeting in the West. Over 400 persons joined the Association. Nearly 200 papers were presented; it is not derogatory to any author to say that these papers were of average interest only, and comprised no startling announcements. The general management was very successful. The chief feature of the meeting was the adoption of the important changes in the constitution which are expected to simplify business in the future. If any complaint can be made, it is of the rather generous disposition on the part of the Sectional Committees towards authors whose productions are of doubtful novelty and uncertain value. There is a tendency also to overrun the allotted time; papers for which twenty-five minutes are asked consume seventy minutes, and those of ten minutes extend to thirty minutes. The remedy of this evil lies with the chairmen of the sections, and it is hoped that they will hereafter exert their powers more frequently. The social features of the meeting were very enjoyable; the reception at Highland House, and the daily lunches served in the Exhibition building brought together citizens and members in pleasant intercourse.

Prof. Wm. B. Rogers of Boston, the first presiding officer of the Association, was elected an Honorary Fellow, on the unanimous recommendation of both Sections A and B. Prof. Rogers is the first Honorary Fellow chosen by the Association.

The amendments to the constitution proposed at the Boston meeting were adopted almost unanimously. They provide for the formation of nine sections, as follows :—A, Mathematics and Astronomy; B, Physics; C, Chemistry; D, Mechanical Science; E, Geology and Geography; F, Biology; G, Histology and Microscopy; H, Anthropology; I, Economic Science and Statistics.

Each of the above Sections is to have its own chairman, who is also Vice-President of the Society, and its own Secretary. The amended constitution also creates the office of Assistant-General Secretary, makes certain changes in the composition of the Standing Committee,

and of the nominating committee. These alterations make the organisation more like that of the British Association for the Advancement of Science, and became necessary on account of the recent rapid growth of the Association. The membership has doubled within two years, being now about 1800.

The recommendation of the Standing Committee to meet in 1882 at Montreal was adopted with acclamation. The invitation from Minneapolis for 1883 was referred to the Standing Committee.

The Association elected Dr. J. W. Dawson of Montreal President for the ensuing year. The time of meeting was fixed for the fourth Wednesday in August, 1882. Nearly seventy Fellows were elected by ballot, and the following officers for 1882, in accordance with the recommendation of the Nominating Committee, were unanimously elected :—

Officers for 1882. Vice-presidents : Section A, Mathematics and Astronomy, Prof. William Harkness, U.S.N. ; Section B, Physics, Prof. T. C. Mendenhall of Columbus; Section C, Chemistry, Prof. H. Carrington Bolton, Ph.D, of Hartford, Conn. ; Section D, Mechanical Science, Prof. W. P. Trowbridge, Ph.D., of Columbia College, New York ; Section E, Geology, Prof. E. T. Cox of San Francisco ; Section F, Biology, Capt. W. H. Dall of Washington, D.C. ; Section G, Histology and Microscopy, Prof. A. H. Tuttle of Columbus, Ohio ; Section H, Anthropology, Prof. Daniel Wilson of Toronto ; Section I, Economic Science and Statistics, E. B. Elliot of Washington, D.C.

We have already (vol. xxiv. p. 455) referred to the action taken by the Association in reference to science degrees.

The following are some of the principal papers read at the meeting :—

In Section A : Magnetic survey of Missouri, by Prof. F. E. Nipher ; on the methods of determining the solar parallax with special reference to the coming transit of Venus, by Prof. William Harkness ; on the wave-lengths of the principal lines of the solar spectrum, by Prof. T. C. Mendenhall ; experiments to determine the comparative strength of globes and cylinders of the same diameter and thickness of sides, by Samuel Marsden ; historic notes on cosmic physiology, by Dr. T. Sterry Hunt ; upon the use of the induction balance as a means of determining the location of leaden bullets imbedded in the human body, by Prof. Alex. Graham Bell ; upon a new form of electric probe, by the same ; on a new method of applying water-power of small head to effect the direct compression of air to any required high pressure, by Prof. H. T. Eddy ; the needle telephone, a new instrument by Dr. Goodman of Louisville, Ky., by Dr. J. Lawrence Smith ; an improved sonometer, by W. Le Conte Stevens ; on the great outburst in comet *b*, 1881, observed at the Cincinnati Observatory, by Prof. Ormond Stone ; method of determining the value of the solar parallax from meridian observations of Mars, by Prof. J. K. Eastman ; numbers of cometary orbits relative to perihelion distance, by Prof. H. A. Newton ; numerical elements of the orbits of the seven electrical vortices to whose motions atmospheric storms are principally due, with the processes by which they have been derived, and examples given of the application of the formula by which their positions on the surface of the earth can be computed for any given time, by Thomas Bassnett ; a preliminary investigation of the two causes of lateral deviation of spherical projectiles, based on the kinetic theory of gases, by Prof. H. T. Eddy ; note on the theory of the flight of elongated projectiles, by Prof. H. T. Eddy ; on the mechanical principles involved in the flight of the boomerang, by Prof. H. T. Eddy ; the electrophore and electric lighting, by Mr. E. B. Elliott ; nodular concretions in meteoric iron, bearing on the origin of same, by Dr. J. Lawrence Smith ; an anomalous magnetic property of a specimen of iron, by Dr. J. Lawrence Smith ; on the errors to which self-registering clinical thermometers are liable, by Dr. Leonard Waldo ; a new radiometer, by Dr. H. Carmichael ; a new differential thermometer, by Dr. H. Carmichael ; note on an experimental determination of the value of π, by Prof. T. C. Mendenhall ; remarks upon, and an exhibition of, Japanese magic mirrors, by the same ; on standard time, by E. B. Elliott ; note on a comparison of Newcomb's tables of Uranus and Neptune, with those of the same planets by Leverrier, by D. P. Todd ; universal energy of light, by Pliny Earle Chase ; electricity, magnetism, gravitation—their phenomena considered as the manifestations of one force, by S. S. Parsons.

In Section B : On the influence of the structure of the nerve-fibres upon the production and conduction of nerve-force, by H. D. Schmidt ; on the action of pilocarpin in changing the colour of the human hair, by Dr. D. W. Prentiss ; the unification of geological nomenclature, by Dr. R. Owen ; the life-unit in plants, by Prof. B. D. Halsted ; recent discoveries, measurements, and temperature observations made in Mammoth Cave, Ky., by Rev. H. C. Hovey ; influence of forests upon streams, by David D. Thompson ; note on the segmentation of the vertebrate body, by Charles Sedgwick Minot ; phenomena of growth in plants, by D. P. Penhallow ; the recurrence of faunas in the Devonian rocks of New York, by H. S. Williams ; a contribution to Croll's theory of secular climatal changes, by W. J. McGee ; the evidence from the drift of Ohio in regard to the origin of Lake Erie, by E. W. Claypole ; on some relations of birds and insects, by S. A. Forbes ; Niagara River, its cañon, depth, and wear, by Wm. Hosea Ballou ; evolution and its place in geology, by Edward S. Edmunds.

In Section C : Is the law of repetition the dynamic law underlying the science of chemistry? by Miss V. K. Bowers ; evidences of atomic motion within molecules in liquids, as based upon the speed of chemical action, by Prof. R. B. Warder ; the constitution of the "atom" of science, by Mrs. A. B. Blackwell ; the sources of nitrogen in plants, by Prof. W. O. Atwater ; notes in experimental chemistry, by Prof. A. B. Prescott ; determination of phosphorus in iron, by Dr. J. Lawrence Smith ; the liquefaction of glass in contact with water at 250° C., by Prof. H. Carmichael ; the chemistry of fish and invertebrates, by Prof. W. O. Atwater ; notes in experimental chemistry, by Prof. Albert B. Prescott ; the quantitative estimation of nitrogen, by Prof. W. O. Atwater ; the quantitative estimation of chlorine, by Prof. W. O. Atwater ; the nitrogenous constituents of grasses, by Clifford Richardson.

In Section D (Anthropology) : Animal myths of the Iroquois, by Mrs. Erminnie A. Smith ; antiquity of man in America, by W. de Haas ; progress of archæological research, by W. de Haas ; the mound builders : an inquiry into their assumed southern origin, by W. de Haas.

In Section E (Microscopy) : On a convenient method of expressing micrometrically the relation between English and metric units of length on the same scale, by William A. Rogers and George F. Ballou.

In Section F (Entomology) ; On the length of life of butterflies, by Prof. W. H. Edwards ; on the life duration of the Heterocera (moths), by Prof. J. A. Lintner ; how does the bee extend its tongue? by A. J. Cook ; the egg-case of *Hydrophilus triangularis*, by Dr. C. V. Riley ; on the oviposition of *Prodoxus decipiens*, by the same ; the cocoon of Gyrinus, by the same ; suggestions of co-operation in furthering the study of entomology, by Prof. B. P. Mann.

THE BRITISH ASSOCIATION

REPORTS

Report of the Committee on Tidal Observations in the English Channel and the North Sea, by J. N. Shoolbred.—In the report it was stated that no official reply had been received by the Committee as to having an international datum for observations, or as to maritime governments giving facilities for detailed observations. The Committee urged the desirability of carrying out a series of observations on the Azores. The Portuguese Government had established a station for registering tides, as had also our own Government at Dover. The Committee hoped before long to have a series of observations giving most important results.

Report of the Committee for Underground Temperature, by Prof. Everett.—In the report it was stated that the temperature varied from one degree for 30 feet to one degree for 100 feet in going down beneath the surface of the earth in different places. During the past year observations have been made in the East Manchester coal field, the Talavgoch lead mine, Flintshire, and at the Radstock collieries, Bath. With regard to the observations in the East Manchester coal-field, these were respectively

taken at Ashton Moss, Bredbury, and Nook Pit: the temperatures were as follows:—

Place.	Depth. Feet.	Temperature.
Ashton Moss	2790	85·3
Bredbury Colliery	1020	62·0
Nook Pit	1050	62·3

The increments of temperature would be as follows:—

Place.	Depth. Feet.	Increase of temperature.
Ashton Moss	2790	36·3
Bredbury Colliery	1020	13
Nook Pit	1050	13·3

This gave for each degree of increase, Ashton Moss 76·9 feet, Bredbury 78·5, and Nook Pit, 79 feet. In Flintshire the observations showed great irregularity last year, and the observations taken this year increased the irregularity. The observations were taken at a place in the lead mine at a depth of 660 feet; at this depth the temperature was 62°, 48° being assumed to be the surface temperature which gave an increase of 14° in 660 feet, or 1° in 47 feet. At the Radstock colliery observations were made at three places. The Wells May Pit, 560 feet deep, the Ludlow Pit, 1000 feet, and a third station in the same pit 810 feet deep, the surface temperature being assumed 50°, the rate of increase was found to be 11°·7 in 560 feet, and 13° for both 810 feet and 1000 feet.

Mr. W. M. Hicks read his report *On Recent Progress in Hydrodynamics*, which he related to the investigations undertaken since 1846, the date of Prof. Stokes's well-known report.

A Report of the Committee on Fundamental Invariants, by Prof. Sylvester, was read.

Report of Committee on Mathematical Tables, by James Glaisher, F.R.S.—The author stated that the factor table for the sixth million was now completed and stereotyped, and he had the pleasure to exhibit to the section proofs of the whole of this million taken from the stereotyped plates. The factor tables for the fourth and fifth millions had been already published, so that now the gap of three millions between the tables of Burckhardt (1817) and those of Dase (1861) was completely filled up. The introduction to the sixth million would shortly be completed, when this volume would appear.

Report on the Tertiary Flora of the Basalt of the North of Ireland, drawn up and illustrated by W. H. Bailey, Geological Survey of Ireland.

Mr. Sclater, in the absence of Mr. Thiselton Dyer, presented the *Report of the Committee appointed for the Purpose of Investigating the Natural History of Timor-laut.*—In a letter addressed to Sir Joseph Hooker, director of the Royal Gardens, Kew, Mr. H. O. Forbes had written from Sumatra, offering, if some assistance could be forwarded to him, to attempt an expedition to Timor-laut, for the purpose of investigating its natural history—"an object," as Mr. Forbes stated, "the accomplishment of which is desired both by botanists and zoologists." An application on Mr. Forbes's behalf was accordingly made to the British Association, and a sum of 50*l.* was voted by the General Committee at the Swansea Meeting to be placed at the disposal of the Committee, to whom the conduct of the matter was intrusted. The action taken by the Association was communicated to Mr. Forbes, and a letter was received in reply. This was the most recent information which the Committee possessed as to his plans. It was somewhat doubtful whether, owing to insufficiency of funds, he was able to start. At any rate, the grant made at Swansea remained in the hands of the Committee. The expedition was obviously attended with some difficulty, if not danger. Its success must be largely dependent on fortunate accident. The Committee, however, thought that there was a reasonable chance of the work being done, and therefore recommended their reappointment, and that a further sum of 100*l.* be placed at their disposal.

The *Report of the Committee on the Natural History of Socotra* gave an account of the progress made in working out Prof. Bayley Balfour's collections, and recommended its reappointment with a somewhat extended sphere, so as to embrace the adjoining highlands of Arabia and Somali Land.

A Report by Mr. R. J. Usher *On Caves and Kitchen-Middens at Cappagh, County Waterford*, described an extensive series of kitchen-middens which had been excavated with the aid of the Association grant. One of these filled a cave of considerable extent, the more ancient parts of which had not been yet explored. The excavated parts yielded large quantities of bones and implements which did not furnish very striking results.

The *Report of the Committee for the Investigation of the Influence of Bodily Exercise on the Elimination of Nitrogen*, presented by Mr. North, detailed the delays in commencing the actual investigation, owing to the necessary devising and construction of instruments. It was hoped however that valuable results might be obtained before the meeting at Southampton.

The *Report of the Committee on the Zoological Station at Naples* was read by Mr. Percy Sladen. He stated that the laboratory had added micro-spectroscopic and polariscopic apparatus, a new Du Bois-Reymond's section apparatus, and a valuable series of chemico-physiological apparatus; and the breeding and aërating apparatus have been successfully worked. Two of the monographs of the Fauna and Flora of the Gulf of Naples have been published in the last year, viz., the Ctenophora by Dr. Carl Chun, and the species of the genus Fierasfer by Dr. Carlo Emery. The monographs on the Pantopoda, by Dr. Dohrn; the Corallines, by Solms-Laubach; and on Balanoglossus, by Dr. J. W. Spengel, are in a forward state. The *Zoologische Jahresberichte* for 1880 is in the press, and will be issued in four parts. The novel method of investigating the sea-bottom by means of diving apparatus has been successfully used in many clear portions of the bed near Naples. Many details of improvement have been made, and many fissures and cavities may be explored which are inaccessible to the trawl or the dredge, and sponges, hydroids, actiniæ, bryozoa and planarians, nudibranchs and algæ may be obtained *in situ*. During the year Mr. Allen Harker has studied at the British Association table, chiefly on the circulation and respiration in the polychætous annelids; also Mr. F. G. Penro e, who investigated the circulation in *Solen legumen*. Mr. P. Geddes desires to prosecute special researches during the coming year, and will be accompanied by an assistant. Thirty-four naturalists have worked at the station during the year, many memoirs have been published, large quantities of specimens have been sent to foreign museums and naturalists, as well as micro copical preparations.

Report of the Committee, consisting of Mr. James Heywood, F.R.S., Mr. William Shaen, Mr. Stephen Bourne, Mr. Robert Wilkinson, the Rev. W. Delany, Mr. N. Story Maskelyne, M.P., F.R.S., Dr. Silvanus P. Thompson, Miss Lydia E. Becker, Sir John Lubbock, Bart., M.P., F.R.S., Prof. A. W. Williamson F.R.S., Mrs. Augusta Webster, and Dr. J. H. Gladstone, F.R.S. (Secretary), on the manner in which Rudimentary Science should be taught, and how Examinations should be held therein, in Elementary Schools.—Rudimentary science is taught in public elementary schools in the form of—I. Object lessons; II. Class subjects under article 19, c. 1, of the New Code; III. Specific subjects under Schedule IV. of the same Code; IV. Science subjects preparatory to entering classes in connection with science schools.

I. Object lessons are attempted in a large number of infant schools, and in some instances are very effective in developing the perceptive powers and intelligence of the children; but in other cases they are too formal, and left too much to the junior teachers. In boys' and girls' schools they frequently appear upon the time-table, especially where, as in the schools of the London Board, they are looked upon as a necessary part of the instruction: but they are generally given in an unsystematic, and often in an unsatisfactory manner.

II. The teaching of science as a class subject under the Code only commenced last October, and thus no examinations have yet been held under it. Natural history, physical geography, natural philosophy, &c., are mentioned in article 19, c. 1, and it is stated that the instruction should be given "through reading lessons, illustrated, if necessary, by maps, diagrams, specimens, &c."; but the teachers are limited to two subjects, and the old subjects, grammar, history, geography, and needlework naturally retain their place in the great majority of the schools. Suitable reading-books for these rudimentary science subjects have scarcely yet came into existence.

III. The specific subjects of the fourth schedule include mechanics, animal physiology, physical geography, botany, and domestic economy, but only two subjects may be taken (or three if the child has passed Standard VI.); and the schedule also includes English literature, mathematics, Latin, French, and German. Literature is a general favourite; and domestic

economy is obligatory in girls' schools if any specific subject is taken at all; so that the chance of any of the others being introduced is very much diminished. It must also be remembered that these subjects are only allowed to be taught to children in the Fourth Standard and upwards; while only about one-fifth of the children in the boys' and girls' schools are to be found at present in these standards. According to the Report of the Committee of Council for Education recently issued, there were 476,761 children presented for examination in these standards, of whom the following numbers only were examined in the science subjects:—

Mechanics	2,109
Animal physiology	24,725
Physical geography	34,288
Botany	1,853
Domestic economy	50,797

Out of 489 boys' and girls' departments under the London School Board, the specific science subjects were taken up, as follows, during the year 1880:—

Mechanics in	4 departments
Animal physiology in	123 ,,
Physical geography in	112 ,,
Botany in	9 ,,
Domestic economy	172 ,,

Mr. Hance of the Liverpool School Board has favoured us with an account of the systematic scientific instruction which is given in the Board schools of that town by a special science staff. The subject selected for the boys is mechanics as defined in the New Code, with a considerable development in the direction of elementary physics. It has been in operation since 1877, and the results for the year 1880-81 are given in the following table:—

Year 1880-81.	Number presented.	Number passed.	Percentage of passes.
Stage I.	797 ...	442 ...	55·46
,, II.	398 ...	261 ...	65·59
,, III.... ...	122 ...	82 ...	67·21
Total... ...	1317 ...	785 ...	59·6

Domestic economy is also taught to the girls in a similar manner. In Birmingham 1200 scholars are receiving scientific instruction in the schools of the Board, and it is stated that the teachers uniformly find that "it added interest to the work of the school, that the children were eager to be present, and that the lessons were enjoyed, and were in fact giving new life to the schools." The Board have found the results so satisfactory that they are now furnishing their newest school with a laboratory and lecture room.

IV. As to science-teaching which does not fall under the provisions of the New Code it is not probable that any large amount is attempted. In Manchester, however, the Board gives instruction to 404 children, all of whom have passed Standard VI., the highest ordinary standard, in the following subjects: physiology; acoustics, light, and heat; magnetism and electricity; chemistry; practical chemistry; botany. This teaching is illustrated by means of good apparatus, &c., and has had a very beneficial effect upon the science and art classes of the town. When it is considered that the provisions of the Code naturally form, in almost all cases, the extreme limit of what will be attempted in the schools, it is important that they should be placed as high as possible. This will be a great advantage to the stronger schools, and no disadvantage to the weaker ones, as the higher branches of science-teaching will of course be optional. Your committee have, therefore, arrived at the following conclusions:—

I. *As to object lessons.* That it is very desirable that Her Majesty's Inspectors should take object lessons into account in estimating the teaching given in an infant school; and that they should examine the classes in the graded schools wherever object lessons are given.

II. *As to class subjects.* That the teaching of such subjects as natural history, physical geography, natural philosophy, &c., should not necessarily be "through reading lessons," as oral lessons, "illustrated by maps, diagrams, specimens, &c.," are undoubtedly better when given by a teacher duly qualified to handle these subjects. They are of opinion, also, that it will be desirable to allow a larger number of class subjects to be taken up in any particular school, and to give in such case a proportionately increased grant.

III. *As to specific science subjects.* That a knowledge of the facts of nature is an essential part of the education of every child, and that it should be given continuously during the whole of school life from the baby class to the highest standard. Of course in early years this teaching will be very rudimentary; but by developing the child's powers of perception and comparison it will prepare it for a gradual extension of such knowledge. They consider also that the early teaching must be very general, while the later may be more specific; they think, however, that the science subjects as given in Schedule IV. are fairly open to objection, as being somewhat too ambitious in their nomenclature and in their scope, and that they ought not to be attempted unless the child has had a previous training in natural knowledge before entering the fourth standard. Thus the specific scientific subjects ought not to be distinct, as they practically are at present, from the previous teaching; greater latitude of choice might be allowed in them; and while they should not afford technical instruction they should prepare the way for any technical classes or schools into which the children may subsequently enter. In regard to domestic economy they are of opinion that most of the points embraced in the schedule would be useful to boys as well as to girls.

IV. *As to examinations.* That in the appointment of Her Majesty's Inspectors some knowledge of natural science should be considered as absolutely requisite; that in examining the children they should direct their inquiries so as to elicit not so much their knowledge of special facts as their intelligent acquaintance with the world of nature around them; and that this may be much better done by oral examination than by paper work.

SECTION A—MATHEMATICAL AND PHYSICAL

On the Economy of Metal in Conductors of Electricity, by Sir W. Thomson.—The most economical size of the copper conductor for the electric transmission of energy, whether for the electric light or for the performance of mechanical work, would be found by comparing the annual interest of the money value of the copper with the money value of the energy lost in it annually in the heat generated in it by the electric current. The money value of a stated amount of energy had not yet begun to appear in the City price lists. If 1*d.* were taken as the par value of a horse-power night and day for a year, and allowing for the actual value being greater or less (it might be very much greater or very much less) according to circumstances, it was easy to estimate the right quantity of metal to be put into the conductor to convey a current of any stated strength, such as the ordinary strength of current for the powerful arc light, or the ten-fold strength current (of 240 webers) which he (Sir William Thomson) had referred to in his address as practically suitable for delivering 21,000 horse-power of Niagara at 300 miles from the fall. He remarked that (contrary to a very prevalent impression and belief) the gauge to be chosen for the conductor does not depend on the length of it through which the energy is to be transmitted. It depends solely on the strength of the current to be used, supposing the cost of the metal and of a unit of energy to be determined. Let A be the sectional area of the conductor; s the specific resistance (according to bulk) of the metal; and c the strength of the current to be used. The energy converted into heat and so lost, per second per centimetre, is sc^2/A ergs. Let p be the proportion of the whole time during which, in the course of a year, this current is kept flowing. There being 31½ million seconds in a year, the loss of energy per annum is

$$31{\cdot}5\times10^6 psc^2/A \text{ ergs} \quad . \quad . \quad . \quad (1)$$

The cost of this, if E be the cost of an erg, is

$$31{\cdot}5\times10^6 psc^2E/A \quad . \quad . \quad . \quad (2)$$

Let V be the money value of the metal per cubic centimetre. The cost of possessing it, per centimetre of length of the wire, at 5 per cent. per annum, is

$$VA/20 \quad . \quad . \quad . \quad . \quad (3)$$

Hence the whole annual cost, by interest on the value of the metal, and by loss of energy in it, is

$$\frac{1}{20}VA+\frac{31{\cdot}5\times10^6 psc^2E}{A} \quad . \quad . \quad . \quad (4)$$

The amount of A to make this a minimum (which is also that which makes the two constituents of the loss equal) is as follows:—

$$A=\sqrt{\left(31{\cdot}5\,.\,10^6 psc^2E/\frac{V}{20}\right)}$$
$$=c\sqrt{(63\,.\,10^7 psE/V)} \quad . \quad . \quad (5)$$

Taking 70*l.* per ton as the price of copper of high conductivity (known as "conductivity copper" in the metal market), we have ·00007*l.* as the price of a gramme. Multiplying this by 8·9 (the specific gravity of copper), we find, as the price of a cubic centimetre,

$$V = \cdot 00062l. \quad . \quad . \quad . \quad . \quad (6)$$

and the assumption of 10*l.* as the par value of one horse-power day and night for 365 days gives, as the price of an erg,

$$10l./(31\tfrac{1}{2}\times 10^6\times 74\times 10^8) = \frac{\cdot 1}{23\times 10^{14}} \text{ of } 1l. \quad (7)$$

Supposing the actual price to be at the rate of $e\times 10l.$ for the horse-power year, we have

$$E = \frac{e}{23\times 10^{14}} \text{ of } 1l. \quad . \quad . \quad . \quad (8)$$

Lastly, for the specific resistance of copper we have

$$s = 1640 \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Using (8) and (9) in (5) we find,

$$A = c\sqrt{\frac{63\times 10^7\times 1640\times pe}{23\times 10^{15}\times \cdot 00062}} = c\sqrt{\frac{pe}{1\cdot 38}} \quad . \quad (10)$$

Suppose, for example, $p = \cdot 5$ (that is, electric work through the conductor for twelve hours of every day of the year to be provided for), and $e = 1$. These suppositions correspond fairly well to ordinary electric transmission of energy in towns for light, according to present arrangements. We have—

$$A = c\sqrt{\frac{1}{27\cdot 6}} = \frac{c}{5\cdot 25} = \cdot 19c.$$

That is to say, the sectional area of the wire in centimetres ought to be about a fiftieth of the strength of the current in webers. Thus, for a powerful arc-light current of 21 webers, the sectional area of the leading wire should be ·4 of a square centimetre, and therefore its diameter (if it is a solid round wire) should be ·71 of a centimetre. If we take $e = \frac{1}{27\cdot 6}$, which corresponds to 1900*l.* a year as the cost of 5250 horse-power (see Presidential Address, Section A), and if we take $p = 1$, that is, reckon for continued night and day electric work through the conductor, we have—

$$A = \frac{c}{\sqrt{381}} = \frac{c}{19\cdot 5};$$

and if $c = 24$, $A = 1\cdot 24$, which makes the diameter 1·26 centimetres, or half an inch (as stated in the Presidential Address). But even at Niagara it is not probable that the cost of an erg can be as small as $\frac{1}{2\,8\,0}$ of what we have taken as the par value for England; and probably therefore a larger diameter for the wire than ½ inch will be better economy if so large a current as 240 webers is to be conducted by it.

Illuminating Powers of Incandescent Vacuum Lamps with Measured Potentials and Measured Currents, by Sir William Thomson and James T. Bottomley.—The electromotive force used in these experiments was derived from Faure secondary batteries, kindly supplied for the purpose by the Société la Force et la Lumière in their London office. Two galvanometers were used simultaneously, one (called the *potential galvanometer*) for measuring the difference of potentials between the two terminals of the lamp, the other (called the current galvanometer) for measuring the whole strength of the current through the lamp. The potential galvanometer had for its coil several thousand metres of No. 50 (B.W.G.) silk-covered wire (of which the copper weighs about one-twentieth of a gramme per metre, and therefore has resistance of about 3 ohms per metre). Its electrodes were applied direct on the platinum terminals of the lamp. The current galvanometer had for its coil a single circle, of about 10 centimetres diameter, of thick wire placed in the direct circuit of the lamp, by means of electrodes kept close together to a sufficient distance from the galvanometer to insure no sensible action on the needle except from the circle itself. The directive force on the needle which was produced by a large semicircular horseshoe magnet of small sectional area was about 2½ c.g.s., or fifteen times the earth's horizontal magnetic force in London. This arrangement would have been better for the potential galvanometer also than the plan actually used for it, which need not be described here. The scale of each galvanometer was graduated according to the natural tangent of the angle of deflection, so that the strength of the current was simply proportional to the number read on the scale in each case. Three lamps were used, Nos. II. and III. of a larger size than No. I. The experiment was continued with higher and higher potentials on each lamp till its carbon broke. The illuminating power was measured in the simplest and easiest way (which is also the most accurate and trustworthy), by letting the standard light and the lamp to be measured shed their lights nearly in the same direction on a white ground (a piece of white paper was used); and comparing the shadows of a suitable object (a pencil was used); and varying the distance of the standard light from the white ground till the illuminations of the two shadows were judged equal. The standard used was a regulation "standard candle," burning 120 grains of wax in the hour. The burning was not actually tested by weighing, but it was no doubt very nearly right; nearly enough for our purpose, which was an approximate determination of the illuminating powers of each lamp through a wide range of electric power applied to it. The following results were obtained:—

LAMP No. I.

No. of experiment.	Cells.	Volts.	Webers.	Volts × webers ÷ 10 = kilogram-metres.	Horse-power.	Candles	Candles per horse-power.

3	60	Carbon of lamp broke.					

Some of the irregularities of the results in the preceding tables are very interesting and important, as showing the effect of the

blackening of the glass by volatilisation of the carbon when too high electric power came to be applied. The durability of the lamp at any particular power must be tested by months' experience before the proper intensity for economy can be determined.

On some Uses of Faure's Accumulator in connection with Lighting by Electricity, by Sir W. Thomson.—The largest use of Faure's accumulator in electric lighting was to allow steam or other motive power and dynamos to work economically all day, or throughout the twenty-four hours where the circumstances were such as to render this economical, and storing up energy to be drawn upon when the light was required. There was also a very valuable use of the accumulator in its application as an adjunct to the dynamo, regulating the light-giving current and storing up an irregular surplus in such a manner that stoppage of the engine would not stop the light, but only reduce it slightly, and that there would always be a good residue of two or three hours' supply of full lighting power, or a supply for eight or ten hours of light for a diminished number of lamps. He showed an automatic instrument which he had designed and constructed to break and make the circuit between the Faure battery and the dynamo, so as automatically to fulfil the conditions described in the paper. This instrument also guarded the coils of the dynamo from damage, and the accumulator battery from loss, by the current flowing back, if at any moment the electro-motive force of the dynamo flagged so much as to be overpowered by the battery.

An Analysis of Relationships, by Dr. A. Macfarlane.—The paper contained a summary of the notation and elementary laws of an analytical method of dealing with such questions as, in the simplest cases, may be dealt with graphically by means of the genealogical tree. The subject is a special branch of the algebra of logic, and its development appears to the author to throw much light upon the fundamental principles of that science and to suggest important questions as to the relation of mathematical analysis to ordinary languages. The method has been applied to test the "systems of affinity and consanguinity" of Dr. Morgan of Rochester, New York.

On a Microscope with Arrangements for Illuminating the Sub-Stage, by E. Crossley.—The author stated that, using a bullseye condenser, the light from the lamp is thrown into the hollow horizontal axis of the microscope, and by means of a prism placed in the centre of this axis is reflected forwards in the direction of the axis on which the swinging sub-stage turns. The arm of a swinging sub-stage is made in the form of a box, and carries a second prism on the axis, on which it moves so as to intercept the rays of light coming from the first prism, and reflect them in the direction of the arm or box. At the end of the box is a third prism, which throws the rays of light forward on to the mirror, by means of which they are finally directed to the object on the stage. No change in the position of the microscope on its horizontal axis affects the direction of the light from the lamp, and whatever the position of the swinging sub-stage, whether above or below the stage, the illumination remains constant upon the object. The greatest facility is thus given for illuminating the object at any angle, and also seeing which is most suitable. The prisms used are one-inch, and give sufficient light for a one sixteenth-inch object-glass with a Ross B-eyepiece, a suitable condenser being used beneath the stage.

Observations of Atmospheric Electricity at Kew Observatory during 1880, by G. M. Whipple.—The author having spoken about the work already done, stated that he had devised a modification of Prof. Everett's method, and had constructed a glass scale by means of which curves could be tabulated with great facility. They had commenced tabulating and discussing the accumulated records, and he was able to state some of the facts derived from the curves for 1880. Having determined the atmospheric tension for every hour during the year when measurement of the trace was possible, the diurnal, monthly, and annual variations were computed. The months of maximum tension were January and March, and of minimum tension August and September. From the year's observations it was found that the laws vary in summer and winter; for the summer months the tension was greatest with an east wind and lowest with a north wind, whilst in winter the tension was greatest with north and north-west winds and least with south-east winds. From the results obtained it was found that light winds had a higher potential than strong winds. This, however, was not well marked in summer, but is almost entirely due to winter observations.

On Prof. Phillips' Rainfall Observations made upon York Minster, by G. J. Symons, F.R.S.—The author, referring to the experiments established at York Minster, said that three gauges nearly identical in pattern were placed, one in the museum garden, one on the roof of the museum, and the third on a pole about 9 feet high placed on the centre tower of York Minster. These gauges were measured at various but identical times during the years 1832-1835, and the results were :—

	Total rain.	Ratio.
Museum garden 2 inches above ground ...	21·81 ...	100
Museum roof 44 feet ,, ...	17·39 ...	80
Minster tower 213 feet ,, ...	12·99 ...	60

Prof. Phillips stated the real amount of the diminution of rain at the upper stations depended upon the temperature of the seasons; the diminution did not vary uniformly as the square root of height, being in winter only as the cube root. Prof. Phillips' experiments soon became known, and Prof. Bache of Philadelphia set up four gauges at the angles of a square tower 162 feet high. His experiments were reported to the British Association in 1838. In 1861 Mr. Stanley Jevons made an important theoretical contribution to this investigation; he pointed out the weakness of the different extant theories, and showed that the phenomena observed were all consistent with the theory that the fall of rain was practically identical at all elevations, and that the observed differences were due to the imperfect collection by the gauges; he also stated that towers, buildings, and even the gauge itself, were obstacles to the rain-bearing current of air, and he concluded that less rain would fall on the summit of the obstacle than elsewhere, the surplus being carried forward to the lee side. Similar observations have been made during the last fifteen years, which have also been supplemented by anemometric observations, and these have proved that the difference in the amount collected was always greatest when the wind was strongest. The subject of late has been investigated by Mr. Dines, who placed several gauges 50 feet from the ground on the tower of his house. In 1877 Mr. Dines read a paper, and said that there was no actual decrease at the higher level, but a diminished collection due to eddy; he added that he found a large gauge on the tower caught much more than a small one. Mr. Rogers Field now took the matter up, and setting down the values so as to form curves he showed :—1. That the ratio of the rainfall on the tower to the rainfall on the ground depends on the force and direction of the wind. 2. That when there is no wind the rainfall on the tower is about the same as the rainfall on the ground. 3. That when there is wind the amount of rain falling on the tower will vary on different portions of the tower, the portion nearest the point at which the wind strikes the tower receiving less rain than falls on the ground, and the portion farthest from the point at which the wind strikes the tower receiving the same or more rain than falls on the ground. 4. That the excess of rain falling on the portion of the tower farthest from where the wind strikes will, to a large extent, compensate the deficiency of rain on the portion nearest to where the wind strikes, but whether to a sufficient extent to make the average amount of rain falling on the tower equal to that falling on the ground cannot be determined from these experiments. From these conclusions it is clear that if the building be flat and large, the fall in the middle of the roof ought to be nearly the same as on the ground, and in two instances this is so, first at Messrs. Marshall's factory at Leeds, and secondly Mr. Dines on a roof of 5000 square feet of area. Thus finally experimental evidence has corroborated the views of Mr. Stanley Jevons, given above.

On some of Bell and Tainter's Recent Researches and their Consequences, by W. Lant Carpenter.—The author referred to the researches of Messrs. Graham Bell and Tainter upon the sonorousness of matter under the influence of a beam of intermittent light, and described the receivers employed, in which substances are placed for examination. Porous substances gave louder sounds than dense ones, and those of a dark colour louder than light when a rapidly intermittent beam fell on them. An apparatus had been contrived by Mr. Tainter for measuring the relative sonorous powers of bodies, which was described by the author. He also stated that it had occurred to him that a modification of this apparatus might be employed for audibly estimating the relative intensities of two lights when intermittent beams fell from them upon two precisely similar receivers. The author proposed to call this instrument an audible photometer, and said that some rough experiments had somewhat justified his expectations.

On Magnetic Disturbances, by Prof. W. G. Adams, F.R.S.—The author, in considering magnetic disturbances, stated that certain facts about them had long been known; from the observations of Gauss in 1834 the disturbing power was found to increase in northern latitudes; it was also found that the appearance of a disturbance occurred in several places at the same instant, but with great differences of results. The force seemed to originate at a certain point in the interior of the earth, and the direction of the disturbing force seemed constant, yet great differences were observable at places not remote from one another. Sabine found that these disturbances had daily and yearly variations from their mean values, and that they have an eleven-year period corresponding to the appearance of spots upon the sun. It has been shown by observations that magnetic disturbances and electric currents on the earth are related; these electric currents in the earth have commonly been attributed to changes of temperature. The month of March, 1879, was chosen for a comparison of the photographic records of magnetic disturbances, and records for the whole month were sent from Lisbon, Coimbra, Stonyhurst, Vienna, St. Petersburg, and Bombay in the northern hemisphere, and from Melbourne and the Mauritius in the southern hemisphere. Taking the disturbances on March 15–16, 1879, as an instance, we see that soon after 10 a.m. Greenwich time on the 15th, a disturbance-wave happens, which shows first a diminution and then an increase of horizontal force at St. Petersburg, Vienna, Kew, and Lisbon, and also at Melbourne in Australia. At 9.30 p.m. of the same day a magnetic storm begins, and continues for about an hour. It is felt in the northern and southern hemispheres. At all stations in Europe the horizontal force is increased in the first part of the storm, and then diminished. At Lisbon the vertical force is first increased and then diminished, and at St. Petersburg and Stonyhurst there is a diminution in the vertical force at the same time as at Lisbon. Regarding the declination needles, we find that at St. Petersburg, Melbourne, and Bombay the declination westward is first increased and then diminished, whereas at Kew and Lisbon the motions are in opposite directions. At Bombay and Mauritius, near to, but on opposite sides of, the equator, the declination needles are deflected opposite ways. If we assume that by magnetic induction the earth's magnetism is altered, the position of the magnet which would cause the disturbance must be such that its pole, which attracts the marked end of our needle, must lie at the beginning of the disturbance to the east of Kew and Lisbon, to the north of Vienna, and to the north-west of St. Petersburg; the Lisbon vertical force curve also shows it to be below the surface of the earth. Hence an inductive action equivalent to a change of position of the north magnetic pole towards the geographical pole would account for these changes. The strengthening and weakening of a magnet with its north pole to the north on the meridian of Vienna might account for magnetic changes observed between 9.30 and 10.30 at night, Greenwich time, on March 15, 1879. In attempting to explain this disturbance by currents of electricity or discharges of statical electricity in the air above the needles, we must imagine that at first there is a strong current from the south-west over St. Petersburg, from the west over Vienna, and from the north-west over Kew and Lisbon, the vertical force needle at Lisbon showing that the current from the north-west lies somewhat to the east of Lisbon; that at the Mauritius this current is from the north, and at Bombay from the south. Thus we must imagine that a current of electricity passes down from the north-west to the south-east, going on towards the east over Vienna, and towards the north-east over St. Petersburg. This must be kept up very much along the same line throughout the first part of the disturbance, and then the current must be altered in strength in the same manner at all stations. An examination of the principal disturbances at Kew and at St. Petersburg seems to show that (1) a diminution in the horizontal force is accompanied by greater easterly deflections of the declination needle at St. Petersburg than at Kew; (2) increase of horizontal force is accompanied by greater westerly deflections at St. Petersburg than at Kew, or is sometimes accompanied by a westerly deflection at St. Petersburg and an easterly deflection at Kew. Only moderate disturbances have already been considered, and the author now treats of a much larger magnetic storm which began at 10.20 a.m. Greenwich time on August 11. This storm may be divided into three storms: one lasting from 10.20 on the 11th to 1 a.m. on the 12th; a second from 11.30 a.m. on the 12th to 7.20 a.m. on the 13th; and the third from 11.50 a.m. on the 13th to 7 to 8 a.m. on the 14th of August. The first storm began on August 11, at the same instant at all stations. There is a decided similarity, especially in the horizontal force curves, throughout the first part of this storm, and certain points in it stand out prominently. The deflections are alike at Lisbon, Kew, Vienna, St. Petersburg, and after the first very sudden deflection at Toronto also. The greatest effect is produced at St. Petersburg; the similarity between the large disturbances at Vienna and Toronto, in Canada, places differing about six and a half hours in time, is remarkable. About 11.45 p.m. and 2.40 p.m. there are very remarkable points of agreement. From about 4.30 p.m. to 8 p.m. Greenwich time, *i.e.* from about 11 a.m to 2.30 p.m. Toronto time, the deflections are opposed at Toronto and at Vienna or Kew. This would point rather to solar action as the cause of the disturbance. At 9 p.m. the disturbances are all in the same direction, but about 11 p.m., whilst St. Petersburg agrees in direction with the others in a very violent phase of the storm, at Toronto the direction of the deflections is reversed, and this reversal of curves continues until about the end of the first of the three storms. The second storm, the most remarkable of the three, began about 11.30 a.m. on the 12th, and lasted until the next morning. At Toronto the line goes off the edge of the paper on which the photographic record is taken. At Vienna and Melbourne the motion is so rapid that the plate is not sensitive enough to receive the impressions. At 12.20 midday, the time of greatest disturbance at Lisbon and at Zi-ka-Wei near Shanghai in China, two places nine hours different and nearly in the same latitude, the vertical force is increased in precisely the same fashion. At St. Petersburg the change in the horizontal force was one thirty-fifth part of the whole horizontal force, and the total force was changed to about one-eightieth part of its full value. These magnetic changes are so large as to be quite comparable, as we see, with the earth's total force, so that any cause which is shown to be incompetent from the nature of things to produce the one can hardly be held to account for the other.

The number of mathematicians who attended the meeting was very remarkable, and among the foreigners present may be mentioned Messrs. Halphen, Chemin, Rudolf Sturm, Cyparissos Stephanos, and W. Woolsey Johnson (Annapolis, U.S.). A separate mathematical department was formed, which met on three days, and more than thirty papers on pure mathematical subjects were read, many of them being of great interest. Prof. Halphen made a communication on Steiner's theorem relative to the positions of the centres of conics passing through three given points, and gave an elegant extension of the theorem to distinguish the cases in which the three points lay on the same or opposite branches of the curve. He also made communications on the subject of linear differential equations and hypergeometrical series; and in a fourth paper he considered the number of aspects in which points in a plane may be viewed. He showed that two points may be thus viewed in six ways, that four points can be viewed in nine ways, and illustrated this by a diagram, and extended the theorem to five points Prof. Sturm communicated an elaborate memoir on curves of double curvature, relating to the researches of Cayley and Halphen, which was ordered to be printed *in extenso* among the reports. M. Stephanos read several papers, in one of which he showed that the different homographies which exist upon a straight line, and which are triply infinite in number, may be identified with the points of space. A simple and beautiful representation of the particulars of these systems was thus obtained.

The other papers included communications by Prof. Cayley, *On the Transformation of Elliptic Functions, and on Abel's Theorem;* by Prof. H. J. S. Smith, *On the Differential Equations satisfied by the Modular Equations, and on the Theory of the Multiplier in the Transformation of Elliptic Functions;* by Mr. J. W. L. Glaisher, *On the q-Series in Elliptic Functions*; by Dr. Hirst, *On Consequences of the Second Order and Second Class*; and by Prof. R. S. Ball, *On the Application of non-Euclidean Space to a Problem in Kinematics, and an Extension of the Theory of Screws to the Dynamics of any Material System.*

SECTION B—CHEMICAL SCIENCE

The Present State of Chemical Nomenclature, by Prof. A. W. Williamson, Ph.D., F.R.S.—The author stated there were perhaps few departments of science in which such definite principles had been adopted, and to a great extent this applied to the
